Introduction

This module is designed to provide information and demonstrate the application of basic microbiology. Participants will enhance their ability to identify potential food hazards, evaluate the adequacy of and discuss the proper control methods for these hazards.

Overview of Microbiology

Objective

On completion of this module, participants will be able to:

- Identify the types of microorganisms found on food
- Identify factors essential for the growth of microorganisms
- Identify factors used to control the growth of microorganisms
- Discuss the types of illness associated with food poisoning

Introduction

Microbiology is a broad term that covers the study of organisms that were not observed before the advent of the microscope. For our purposes in this course, this means bacteria, yeast, mold, viruses, and parasites. This module on general microbiology will address mainly bacteria but much of the information provided also applies to controlling yeast and molds. This course will focus on pathogens, those organisms that are capable of causing disease. Specific bacteria, virus, and parasites will be addressed.

Foodborne illness takes quite a toll. There may be as many as 33 million cases of foodborne illness in the United States annually, with an estimated 9,000 deaths. Knowledge of microbiology is essential to you as sanitarians and your role in preventing foodborne disease. An understanding of microbial growth and the factors influencing growth will allow you to assess whether appropriate controls are present to prevent foodborne illness.

Not all microorganisms are alike. While some are pathogens, others cause spoilage, which results in objectionable textures and odors in a food. And some organisms are actually beneficial; they are used to make products like cheese, bread, pickles, yogurt, beer and wine.

Microorganisms are so small that most of them must be magnified about 1,000 times before they can be seen through a microscope. Using an average-sized bacterium as an example, about 1,000 could be placed

side-by-side on the period at the end of a sentence. Consider a drop of milk. In spoiled milk there are about 50 million organisms per milliliter, or a total population of about 50 billion organisms in a quart. You can put all 50 billion in that one-drop.

Fungi

Yeasts and molds are collectively called <u>fungi</u>. These organisms grow under conditions in which many bacteria cannot, such as low pH and low water activity.

Molds have many cells that make up a tangled mass of thread like structures called mycelium. Individual threads are called hypha. The most common molds grow by elongation of the hyphae and reproduce by fragmentation of the hyphae or production of spores.

<u>Spores</u> are a dormant form of a microorganism that are generally formed in response to adverse environmental conditions. Some bacteria produce spores too, and some of these are of great significance in the food industry due to their highly resistant nature. While some molds are used in food processing, as in the manufacture of specialty cheeses such as Blue cheese, molds are also involved in food spoilage and some species produce <u>mycotoxins</u>, poisonous substances that can have serious health consequences.

Yeasts are single cells and typically larger than bacteria. Most reproduce by budding. Yeasts are used to ferment wine and beer and leaven bread. Fortunately, they are not associated with foodborne disease but do cause spoilage problems in foods such as sauerkraut, fruit juices, syrups, molasses, jellies, meats, beer and wine.

Bacteria are also single cells and generally come in two forms in foods spherical (cocci), or rod-shaped (bacilli). In addition, bacteria can be divided into two groups on the basis of their ability to form, or not to form spores. Spores are a dormant stage in the life cycle of the organisms. They are often compared to a plant seed that will germinate and grow when conditions are favorable. In general spores are extremely resistant to heat, cold, and chemical agents.

Bacterial Growth

Most food preservation techniques used by processors employ knowledge of factors that affect the growth of bacteria. Nutrients, temperature, water activity, pH, chemical inhibitors, and atmosphere all can be used to control growth. Each of these will be addressed individually.

Factors Affecting Growth:

Nutrients Inhibitors

Temperature pH

Water Activity Atmosphere

Nutrients

Bacteria, like any living organism require food and water to carry on their life processes. Nutrients must be in solution before they can be transported into the cells, so water is essential. In general, bacteria also require sources of carbon, nitrogen, sulfur and phosphorous. Some microorganisms have the necessary enzyme systems to transform these few simple materials into the complex substances required for their life processes, while other microorganisms require certain preformed compounds.

The specifics of the nutrient requirements and the actual mechanisms involved in nutrient transport are important and interesting areas of study. But, unless you are a microbiologist or biochemist the details of this can be rather complicated and tedious. From a practical standpoint, since microorganisms require nutrients to grow and proliferate, *proper sanitation* is essential to eliminate food residues, especially on food contact surfaces. Additionally, since microorganisms require nutrients to be in solution for transport into the cell, it is important that the food-processing environment is constructed to prevent the accumulation of standing water.

Bacteria have phenomenal growth rates. They grow through a process of binary fission - splitting in two every 20 to 30 minutes under optimal conditions. We can follow bacterial growth through a 4-phase growth cycle.

Lag Phase:

This is the first phase, where cells may increase in size but the actual number of cells does not increase. Here the bacteria adjust their metabolism to the environment. This occurs when there is a drastic change in temperature or when the bacteria are moved from one medium to another.

Logarithmic Growth Phase:

Also known as the **Log Phase**. Cells actively divide by simple fission: one cell becomes two. During this phase the bacteria experience rapid exponential growth provided the necessary conditions of moisture, warmth and nutrients are present. The time required for a cell to grow and then divide into two cells is termed the generation time or doubling time.

Stationary Phase:

Cell numbers remain constant. Cell growth and cell death are in balance because they are beginning to deplete nutrients and accumulate waste products.

Death Phase:

Cell numbers begin to decline as a result of ongoing depletion of nutrients and the accumulation of toxic metabolic by-products.

The lag phase is very important. If food is handled properly, the bacteria are kept in this phase and not allowed to multiply. Proper sanitation is important to limit available nutrients and thereby prevent bacterial growth.

Temperature

Another essential factor that affects the growth of bacteria is temperature. Microbial growth can occur over a wide range of temperatures from about 14°F to 194°F. Organisms are divided into three groups based on their temperature growth range:

	Temperature		
	Optimum	Range	
Psychrophile	< 68°F	32° - 86°F	
Mesophile Includes psychrotrophs	98°F	50° - 110°F	
Thermophile	131°F	110° - 194°F	

Psychrophiles grow at or near refrigeration temperatures or 32°F – 86 °F. Mesophiles grow at or near room temperatures, 50°F – 110°F. Thermophiles grow at hot temperatures above 110 °F.

In addition to these three terms, there is also the designation <u>psychrotroph</u>. Their optimal growth temperature is in the mesophilic range but they are capable of growth at refrigeration temperatures.

Most of the microorganisms of public health concern in foods are mesophiles and their optimum growth temperature corresponds to human body temperature. Typically, the higher the temperature (within the normal growth range), the more rapid the growth of the organism. This can be explained by the fact that growth is catalyzed by enzymatic reactions and the rule of thumb is that with every 18°F rise in temperature, the catalytic rate of an enzyme doubles.

Time/Temperature

It is not just the temperature that is the problem; it is the total time of exposure at these temperatures that needs to be controlled. The goal is to minimize the <u>time</u> of exposure of foods to temperatures in the mesophilic range. It is recommended that foods be kept below 40°F or above 140°F. In many situations it may be impossible to completely avoid product exposure to mesophilic temperatures.

Water Activity (a_w)

Water (a_w) activity refers to the availability of water to the organism. Water activity is directly related to the vapor pressure of the water in a solution and is determined by measuring the equilibrium relative humidity of the air over the solution in a closed container. Relative humidity divided by 100 equals the water activity.

$$(a_w) = RH/100$$

If you have a closed container of water, the air over the water becomes saturated. The relative humidity is 100% which equals an $a_{\rm w}$ of 1.0. So water has a water activity of 1.0. Foods are more complex systems so not all the water in the food is available to microorganisms. Think of water activity as water availability. Water molecules are loosely oriented in pure water and they are readily available to microorganisms. When we add substances like salt and sugar, the water molecules orient themselves to the added substance, and the properties of the entire solution change. The water is bound, and less available to microorganisms.

Foods vary in their water activity. See Table 1: Principal Groups of Foods Based on $A_{\text{w.}}$

Table 1
Principal Groups of Foods Based on a_w

0.98 and above	Below 0.98 to 0.93	Below 0.93 to 0.85	Below 0.85 to 0.60	Below 0.60
Fresh meats and fish Fresh fruits and vegetables Milk and other beverages Canned vegetables in brine Canned fruit in light syrup	Evaporated milk Tomato paste Lightly salted fish, pork and beef products Canned cured meats Fermented sausages (not dried) Cooked sausages Processed cheese Gouda cheese Canned fruits in heavy syrup Bread	Dry or fermented sausage Dried beef Raw ham Aged cheddar cheese Sweetened condensed milk	Intermediate moisture foods Dried fruits Flour Cereals Jam and jellies Molasses Heavy salted fish Meat extract Nuts	Confectionery Chocolate Honey Noodles Crackers Potato Chips Dried egg, milk, and vegetables

Microbial Ecology of Foods, Volume 1, Factors Affecting Life and Death of Microorganisms. International Commission on Microbiological Specifications for Foods. Academic Press, 1980.

Fresh meats, fish, fruits and vegetables have a water activity of 0.98 or above. Foods like evaporated milk, cured meat, processed cheese, and bread range between 0.93 and 0.98. Dried meat, aged cheddar cheese, and sweetened condensed milk are above 0.85, but below 0.93. Dried Fruit, cereal, flour, jams and jellies, heavily salted fish, and nuts are intermediate moisture foods, in the range of 0.60 to 0.85. Chocolate, honey and noodles are all below 0.60 water activity.

Most bacteria, including those of public health significance, will not grow when the water activity is 0.85 or less. Many yeast and molds can grow below this level but this is a spoilage concern and generally not a food safety concern.

Inhibitors

Foods can contain chemicals that are either natural or added that restrict or prevent the growth of microorganisms. Salt is a good example of an added chemical that can inhibit the growth of bacteria. Chemical preservatives like sodium nitrite, sodium benzoate and calcium propionate can also inhibit the growth of microorganisms.

рН

Another factor that can control the growth of bacteria is pH. pH is expressed as the negative logarithm of the hydrogen ion concentration.

$[pH = (-log of the [H^+])]$

If you do not understand that, pH shows how acid a food is. Most bacteria don't grow very well in acid foods. pH ranges from 0 to 14, with 7 being neutral. Foods with a pH of 4.6 and below are considered acid foods, like most fruit juices. Foods with a pH above 4.6 are said to be low acid, like meats and vegetables.

pH RANGES FOR GROWTH OF MICROORGANISMS		
Bacteria (gram+)	4.0 to 8.5	
Bacteria (gram -)	4.5 to 9.0	
Molds	1.5 to 9.0	
Yeast	2.0 to 8.5	

Microorganisms can only grow at certain pH levels. Mold and yeast can grow over a broad range of pH. Bacteria are more restricted. Gram positive bacteria grow in a pH range of 4 to 8.5 and Gram negative grows between 4.5 and 9.0. So you can use pH to control the growth of bacteria. Food is considered to be in a safe pH range - or shelf stable - when the final pH is 4.6 or below.

Gram Positive & Gram Negative

"Gram positive" and "Gram negative" are designations that microbiologists use to distinguish different types of bacteria. Different bacteria have different cell walls. To make bacteria stand out under a microscope, a stain is used. Bacteria with different cell walls take up the stain differently. Gram positive bacteria appear blue, and Gram negative appear red.

This tells the microbiologist some things about the bacteria present in a food. For example, in the pH chart you can see that Gram positive bacteria

are a little more tolerant of acid conditions. These bacteria are generally a little more resistant to heat too. Some of them are spore formers.

In general, Gram negative bacteria include those that are associated with intestinal illness. That brings up something very important. That is how the bacteria associated with foodborne illness affect the body. It relates to how fast a person becomes ill after consuming a food and helps the inspector determine which food and which pathogen may have caused an illness.

Atmosphere

Some bacteria require a specific type of atmosphere for growth. Microorganisms are categorized as aerobes, anaerobes, facultative anaerobes and microaerophilic.

Aerobes require oxygen and include such bacterial genera as *Bacillus*.

Anaerobes grow only in the absence of molecular oxygen. These organisms include clostridia.

Facultative anaerobes, which include most of the other food borne pathogens, can grow whether the environment has oxygen or not.

Microaerophilic is a term applied to organisms, which grow only in reduced oxygen environments.

It is important to understand that microbial pathogens are associated with all of the groups mentioned above. Knowledge of the atmospheres surrounding the food is an especially important consideration in determining which pathogens are likely to be a problem.

Atmospheres & Packaging

Many of the organisms that spoil foods are aerobic. Technologies that are used to extend shelf life do so by altering the atmospheric environment of the food package to prevent the growth of aerobic organisms. These technologies include vacuum packaging, controlled atmosphere packaging, and modified atmospheric packaging. Most pathogens are facultative anaerobes so attempts to control spoilage by changing the atmosphere from aerobic to anaerobic or somewhere in between can be potentially dangerous because by eliminating the competing aerobic flora it can select for pathogens and inhibit those microorganisms that give the tell tale signs of spoilage. A product may not appear spoiled but may be toxic.

Types of Foodborne Illness

There are two types of foodborne illness. One is an infection and the other is an intoxication. The bacteria that cause these are different. They're all considered pathogens but the way they make a person sick is different.

Foodborne Infection

A foodborne infection occurs when the microorganism itself is ingested with the food. The organism establishes itself in the host's body and multiplies. Since the infection is a consequence of growth in the body, the time from ingestion until symptoms occur is relatively long.

Foodborne Intoxication

A foodborne intoxication occurs when specific pathogenic bacteria grow in the food and releases toxins into the food that is subsequently consumed. It is the toxin that makes the person sick. Since the illness is a consequence of absorption of the preformed toxin by the intestinal tract, and not microbial growth in the host's body, symptoms of intoxication have a much more rapid onset than foodborne infections.

Toxicoinfection

A third type is called toxicoinfection, which combines the two. Toxicoinfections are characterized by bacteria that are non-invasive and cause illness by producing toxins *while growing* in the human intestines. The times of onset are generally, but not always, longer than those for intoxications, but less than those for infections.

Laboratory Testing

Very often microbiologists test for indicator organisms as a substitute for testing for pathogens. The ideal indicator organism should be present when pathogens are present, absent when there are no pathogens, occur in greater numbers than the pathogens to provide a safety margin, and be easy to detect.

INDICATOR ORGANISMS: FECAL COLIFORMS

STAPHYLOCOCCI

GEOTRICHUM CANDIDUM

One group of indicator organisms is called the coliform group. Members of this group that grow at elevated temperature are called fecal coliforms. These organisms are found in the gastrointestinal tract of humans and warm blooded animals and have been used as an indicator of human fecal pollution in shellfish and their growing waters, as well as other food commodities. Other examples of indicator groups include staphylococci as an indicator of handling abuse, and Geotrichum *candidum*, the machinery mold, as an indicator of plant insanitation and contaminated equipment.

In the Laboratory

In the laboratory, the microbiologist isolates and identifies the bacteria present. There are specific steps that must be taken to do this. Generally, there are three steps in detecting and identifying bacteria:

Enrichment

Selective agar

Biochemical tests

An enrichment medium is used to favor the growth of the organism you are looking for and to give it a chance to increase in number. You enrich the sample by placing the food product in a medium that has the nutrients discussed earlier that are specific to the type of organism you are trying to isolate.

Then, you place a portion of the enrichment into a medium that selects for the desired organism. This medium contains some of the control mechanisms that were mentioned above (salt, an adjusted pH, or other chemicals or antibiotics) which will select for the organism you want, and not allow quite so many other organisms to grow.

You then streak the selective medium onto an agar plate to isolate a pure colony, one that grew from a single cell. This pure colony is essential for subsequent tests since you need to deal with one organism at a time.

The next step is to subject the isolated colony to biochemical tests that are specific to the type of organism you are looking for and that will confirm that you have the organism you think you do. That is the conventional method of looking for organisms. Each step requires time so it takes a while - usually several days - to get results from the laboratory.

Aerobic Plate Count

You also may hear references to "Aerobic Plate Count", also called "Standard Plate Count". This method provides an estimate of the total number of viable aerobic bacteria in a food, rather than a specific organism. It is generally used to determine food quality. In milk products, high counts may indicate that the milk was handled under insanitary conditions. This procedure is based on the assumption that each microbial cell in a sample will form a visible separate colony when mixed with an agar medium and permitted to grow. The food is diluted and placed in the agar medium in petri dishes so that the colonies can be counted. Microbial populations are at best an estimate. They are reported as Colony Forming Units or CFU per gram.

Most Probable Number (MPN)

Another approach to counting bacteria is a statistical method based on probability theory called the "Most probable number" or "MPN". The test material is diluted in a series of dilutions to reach a point where not even a single cell remains in the final dilution. If bacteria are present, the medium in the tube is cloudy, or positive. If no bacteria are present, the medium is clear. The pattern of positive and negative tubes at the different dilutions is used to estimate the concentration of bacteria in the original sample. The microbiologist compares the observed pattern of results with a table of statistical values.

Rapid Methods

Some people are surprised that conventional methods take so long. They think everything is high tech now, providing instant results. Not so, traditional methods are still very much in use. However, it is true that recent advances in biotechnology have dramatically altered the diagnostic procedures used in microbiology. These new "rapid methods" provide simpler and often more sensitive and rapid detection of pathogens and their toxins.

The term "Rapid Method" describes a large variety of detection and identification tests, including those that take a few minutes to perform to those that require days. Basically "rapid" means they're faster than conventional microbiological methods.

The use of rapid methods in foods has some limitations. Foods are so complex, and each one's different. Proteins, fats, oils, and other factors can interfere with the tests. The normal bacteria in a food can also interfere with how well a test works. Low numbers of pathogens in foods are hard to detect. Processing of the food changes the bacterial flora and composition of foods. Most of these problems can be remedied by enriching the sample but that takes time which means it's not as rapid.

Each method must be fully evaluated before it can be applied to food testing. There is a process for doing that but even so the rapid methods that are approved can be used only for presumptive screening of foods, a negative result stands but a positive result must be confirmed using standard methods. The Bacteriological Analytical Manual (BAM) contains all the laboratory methods used by FDA in isolating bacteria from foods.

If you want to *detect* bacteria, rapid methods can only be used after the food sample has been through cultural enrichment. If you want to *identify* bacteria, rapid methods are used only after a pure culture isolate has been obtained from the sample.

Types of Rapid Methods

One type of rapid method is a "miniaturized biochemical identification" device. They are disposable devices that perform 15 to 24 biochemical tests at one time. They are designed to identify specific bacterial species. The microbiologist must work with a pure culture. Some provide results in 4 hours; most within 24 hours. These units simplify the conventional procedure by eliminating tubes and plate media.

Other rapid method kits speed up standard microbiological methods by using special substrates, enzymes or other apparatus. For example, a **Petrifilm plate count card** contains prepared media. You just add your sample at the appropriate dilution and incubate it. You can then count the bacteria present in the sample. It is disposable and eliminates the need to make the agar plates we talked about earlier.

With a positive **MUG test** kit a special chemical reaction alerts the microbiologist that the organism he's looking for is present. One type of MUG test kit is called a Colicomplete test. The discs are impregnated with two chemicals that react in the presence of coliforms and *E. coli*. You inoculate the tube, add one of the discs and incubate. If a blue color develops you have a presumptive positive for coliforms. You then shine a UV light on the tube. If the tube fluoresces you have a presumptive positive for *E. coli*.

Some of the rapid methods involve using antibodies, nucleic acids or robotics to detect pathogens and toxins. Of these, the antibodies are most versatile and are used in various test kits. They take advantage of antibody-antigen interactions that are specific to a particular pathogen. A

latex agglutination test works that way. If the reaction is positive, the latex beads cause the bacteria to clump.

The ELISA test stands for "enzyme linked immunosorbent assay". It is another test that relies on antibody antigen interaction. The final result shows as a color change that can be easily read by the microbiologist. ELISA tests can be used to detect and quantify pathogens and toxins.

A system called **Polymerase Chain Reaction or PCR** uses an enzyme to replicate a portion of a target pathogen's DNA. The reaction involves attaching a marker to the DNA so that it is easily detected. The advantage of this test is that you can detect very small numbers of a particular pathogen. Unfortunately, it does not differentiate between live and dead pathogens.

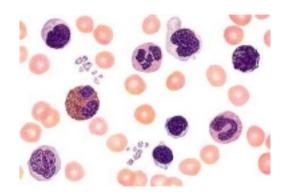

These are only a few examples of what rapid method kits are and can do. The selection of a rapid method test kits depends in part on the organism of concern the food product being tested and the intended purpose of the test.

Foodborne Bacterial Pathogens

Overview

This section contains background information on specific foodborne bacterial pathogens. An understanding of the growth characteristics and sources of bacterial pathogens in foods is essential to conducting a hazard analysis of a food product.

The following bacterial pathogens will be discussed in this section:

Pathogenic bacteria

- Salmonella spp.
- Clostridium botulinum
- Staphylococcus aureus
- Campylobacter jejuni
- Yersinia enterocolitica and Yersinia pseudotuberculosis
- Listeria monocytogenes
- Vibrio cholerae O1
- Vibrio cholerae non-O1
- Vibrio parahaemolyticus and other vibrios
- Vibrio vulnificus
- Clostridium perfringens
- Bacillus cereus
- Aeromonas hydrophila and other spp.

- Plesiomonas shigelloides
- Shigella spp.
- Miscellaneous enterics
- Streptococcus

Enterovirulent Escherichia coli Group (EEC Group)

- Escherichia coli enterotoxigenic (ETEC)
- Escherichia coli enteropathogenic (EPEC)
- Escherichia coli O157:H7 enterohemorrhagic (EHEC)
- Escherichia coli enteroinvasive (EIEC)

Module 1 provided an overview of microbiology. This module will be specific and discuss various foodborne bacterial pathogens. They will be broken into two groups: gram-negative rods, and gram-positive rods and cocci. The pathogens within each group have some similarities in addition to the way they stain. For example, gram negative rods are nonspore formers and tend to have a fecal source. On the other hand, gram-positive rods and cocci can be spore formers and are typically associated with environmental sources like soil and sediments.

Gram Negative Rods

The **gram negative rods** that will be covered in this module are: **Campylobacter jejuni, Yersinia spp., Salmonella spp., Shigella spp., Escherichia coli and Vibrio spp.**, **Plesiomonas shigelloides**

Campylobacter jejuni

1. Name of the Organism:<u>Campylobacter jejuni</u> (formerly known as *Campylobacter fetus* subsp. jejuni)

Campylobacter jejuni is a Gram-negative slender, curved, and motile rod. It is a microaerophilic organism, which means it has a requirement for reduced levels of oxygen. It is relatively fragile, and sensitive to environmental stresses (e.g., 21% oxygen, drying, heating, disinfectants, acidic conditions). Because of its microaerophilic characteristics the organism requires 3 to 5% oxygen and 2 to 10% carbon dioxide for optimal growth conditions. This bacterium is now recognized as an important enteric pathogen. Before 1972, when methods were developed for its isolation from feces, it was believed to be primarily an animal pathogen causing abortion and enteritis in sheep and cattle. Surveys have shown that *C. jejuni* is the leading cause of bacterial diarrheal illness in the United States. It causes more disease than Shigella spp. and Salmonella spp. combined.

Although *C. jejuni* is not carried by healthy individuals in the United States or Europe, it is often isolated from healthy cattle, chickens, birds and even flies. It is sometimes present in non-chlorinated water sources such as streams and ponds.

Because the pathogenic mechanisms of *C. jejuni* are still being studied, it is difficult to differentiate pathogenic from nonpathogenic strains. However, it appears that many of the chicken isolates are pathogens.

<u>Campylobacteriosis</u> is the name of the illness caused by *C. jejuni*. It is also often known as campylobacter enteritis or gastroenteritis.

C. jejuni infection causes diarrhea, which may be watery or sticky and can contain blood (usually occult) and fecal <u>leukocytes</u> (white cells). Other symptoms often present are fever, abdominal pain, nausea, headache and muscle pain. The illness usually occurs 2-5 days after ingestion of the contaminated food or water. Illness generally lasts 7-10 days, but relapses are not uncommon (about 25% of cases). Most infections are self-limiting and are not treated with antibiotics. However, treatment with <u>erythromycin</u> does reduce the length of time that infected individuals shed the bacteria in their feces.

The infective dose of *C. jejuni* is considered to be small. Human feeding studies suggest that about 400-500 bacteria may cause illness in some individuals, while in others, greater numbers are required. A conducted volunteer human feeding study suggests that host susceptibility also dictates infectious dose to some degree. The pathogenic mechanisms of *C. jejuni* are still not completely understood, but it does produce a heatlabile toxin that may cause diarrhea. *C. jejuni* may also be an invasive organism.

C. jejuni is usually present in high numbers in the diarrheal stools of individuals, but isolation requires special antibiotic-containing media and a special microaerophilic atmosphere (5% oxygen). However, most clinical laboratories are equipped to isolate Campylobacter spp. if requested.

C. jejuni frequently contaminates raw chicken. Surveys show that 20 to 100% of retail chickens are contaminated. This is not overly surprising

2. Name of Disease:

6. Frequency of the Disease:

7. Complications:

8. Target Populations:

9. Recovery from Foods:

10. Selected Outbreaks:

since many healthy chickens carry these bacteria in their intestinal tracts. Raw milk is also a source of infections. The bacteria are often carried by healthy cattle and by flies on farms. Non-chlorinated water may also be a source of infections. However, properly cooking chicken, pasteurizing milk, and chlorinating drinking water will kill the bacteria.

C. jejuni is the leading cause of bacterial diarrhea in the U.S. There are probably numbers of cases in excess of the estimated cases of salmonellosis (2- to 4,000,000/year).

Complications are relatively rare, but infections have been associated with reactive arthritis, hemolytic uremic syndrome, and following septicemia, infections of nearly any organ. The estimated case/fatality ratio for all *C. jejuni* infections is 0.1, meaning one death per 1,000 cases. Fatalities are rare in healthy individuals and usually occur in cancer patients or in the otherwise debilitated. Only 20 reported cases of septic abortion induced by *C. jejuni* have been recorded in the literature.

Meningitis, recurrent colitis, acute <u>cholecystitis</u> and Guillain-Barre syndrome are very rare complications.

Although anyone can have a *C. jejuni* infection, children under 5 years and young adults (15-29) are more frequently afflicted than other age groups. Reactive arthritis, a rare complication of these infections, is strongly associated with people who have the <a href="https://example.com/humanlymphocyte.c

Isolation of *C. jejuni* from food is difficult because the bacteria are usually present in very low numbers (unlike the case of diarrheal stools in which 10/6 bacteria/gram is not unusual). The methods require an enrichment broth containing antibiotics, special antibiotic-containing plates and a microaerophilic atmosphere generally a microaerophilic atmosphere with 5% oxygen and an elevated concentration of carbon dioxide (10%). Isolation can take several days to a week.

Usually outbreaks are small (less than 50 people), but in Bennington, VT a large outbreak involving about 2,000 people occurred while the town was temporarily using an non-chlorinated water source as a water supply. Several small outbreaks have been reported among children who were taken on a class trip to a dairy and given raw milk to drink. An outbreak was also associated with consumption of raw clams. However, a survey showed that about 50% of infections are associated with either eating inadequately cooked or recontaminated chicken meat or handling chickens. It is the leading bacterial cause of sporadic (non-clustered cases) diarrheal disease in the U.S.

In April, 1986, an elementary school child was cultured for bacterial pathogens (due to bloody diarrhea), and *C. jejuni* was isolated. Food consumption/gastrointestinal illness questionnaires were administered to other students and faculty at the school. In all, 32 of 172 students reported symptoms of diarrhea (100%), cramps (80%), nausea (51%), fever (29%), vomiting (26%), and bloody stools (14%). The food questionnaire clearly implicated milk as the common source, and a dose/response was evident (those drinking more milk were more likely to be ill). Investigation of the dairy supplying the milk showed that they vat pasteurized the milk at 135°F for 25 minutes rather than the required 145°F for 30 minutes. The dairy processed surplus raw milk for the school, and this milk had a high somatic cell count. Cows from the herd supplying the dairy had *C. jejuni* in their feces. This outbreak points out the variation in symptoms that may occur with campylobacteriosis and the absolute need to adhere to pasteurization time/temperature

standards.

Although other <u>Campylobacter</u> spp. have been implicated in human gastroenteritis (e.g. *C. laridis*, *C. hyointestinalis*), it is believed that 99% of the cases are caused by *C. jejuni*.

Information regarding an outbreak of Campylobacter in New Zealand is found in this MMWR 40(7):1991 Feb 22.

For more information on recent outbreaks see the Morbidity and Mortality Weekly Reports from CDC.

The Food Safety Inspection Service of the U.S. Department of Agriculture has produced a background document on *Campylobacter*.

A <u>Loci index for genome Campylobacter jejuni</u> is available from GenBank.

Back to Foodborne Bacterial Pathogen List

Yersinia enterocolitica

1. Name of the Organism: Yersinia enterocolitica (and Yersinia pseudotuberculosis)

2. Name of Disease:

3. Nature of Disease:

Y. enterocolitica, a small rod-shaped, <u>Gram-negative</u> bacterium, is often isolated from clinical specimens such as wounds, feces, sputum and mesenteric lymph nodes. However, it is not part of the normal human flora. Y. pseudotuberculosis has been isolated from the diseased appendix of humans.

Both organisms have often been isolated from such animals as pigs, birds, beavers, cats, and dogs. Only Y. enterocolitica has been detected in environmental and food sources, such as ponds, lakes, meats, ice cream, and milk. Most isolates have been found not to be pathogenic.

Yersiniosis

There are 3 pathogenic species in the genus Yersinia, but only Y. enterocolitica and Y. pseudotuberculosis cause gastroenteritis. To date, no foodborne outbreaks caused by Y. pseudotuberculosis have been reported in the United States, but human infections transmitted via contaminated water and foods have been reported in Japan. Y. pestis, the causative agent of " the plague," is genetically very similar to Y. pseudotuberculosis but infects humans by routes other than food.

Yersiniosis is frequently characterized by such symptoms as gastroenteritis with diarrhea and/or vomiting; however, fever and abdominal pain are the hallmark symptoms. Yersinia infections mimic appendicitis and mesenteric lymphadenitis, but the bacteria may also cause infections of other sites such as wounds, joints and the urinary tract.

Unknown.

4. Infective dose:

Illness onset is usually between 24 and 48 hours after ingestion, which (with food or drink as vehicle) is the usual route of infection.

Diagnosis of yersiniosis begins with isolation of the organism from the human host's feces, blood, or vomit, and sometimes at the time of appendectomy. Confirmation occurs with the isolation, as well as biochemical and serological identification, of Y. enterocolitica from both the human host and the ingested foodstuff. Diarrhea is reported to occur in about 80% of cases; abdominal pain and fever are the most reliable symptoms.

5. Diagnosis of Human Illness:

Because of the difficulties in isolating yersiniae from feces, several countries rely on serology. Acute and convalescent patient sera are titered against the suspect serotype of Yersinia spp.

Yersiniosis has been misdiagnosed as <u>Crohn's disease</u> (regional enteritis) as well as appendicitis.

Strains of Y. enterocolitica can be found in meats (pork, beef, lamb, etc.), oysters, fish, and raw milk. The exact cause of the food contamination is unknown. However, the prevalence of this organism in the soil and water and in animals such as beavers, pigs, and squirrels, offers ample opportunities for it to enter our food supply. Poor sanitation and improper sterilization techniques by food handlers, including improper storage, cannot be overlooked as contributing to contamination.

6. Associated Foods:

7. Frequency of the Disease:

Yersiniosis does not occur frequently. It is rare unless a breakdown occurs in food processing techniques. CDC estimates that about 17,000 cases occur annually in the USA. Yersiniosis is a far more common disease in Northern Europe, Scandinavia, and Japan.

The major "complication" is the performance of unnecessary appendectomies, since one of the main symptoms of infections is abdominal pain of the lower right quadrant.

Both Y. enterocolitica and Y. pseudotuberculosis have been associated with reactive arthritis, which may occur even in the absence of obvious symptoms. The frequency of such postenteritis arthritic conditions is about 2-3%.

Another complication is <u>bacteremia</u> (entrance of organisms into the blood stream), in which case the possibility of a disseminating disease may occur. This is rare, however, and fatalities are also extremely rare.

The most susceptible populations for the main disease and possible complications are the very young, the debilitated, the very old and persons undergoing immunosuppressive therapy. Those most susceptible to postenteritis arthritis are individuals with the antigen
HLA-B27">HLA-B27 (or related antigens such as
B7).

The isolation method is relatively easy to perform, but in some instances, cold enrichment may be required. Y. enterocolitica can be presumptively identified in 36-48 hours. However, confirmation may take 14-21 days or more. Determination of pathogenicity is more complex. The genes encoding for invasion of mammalian cells are located on the chromosome while a 40-50 MDal plasmid encodes most of the other virulence associated phenotypes. The 40-50 MDal plasmid is present in almost all the pathogenic Yersinia species, and the plasmids appear to be homologous.

1976. A chocolate milk outbreak in Oneida County, N.Y. involving school children (first reported yersiniosis incident in the United States in which a food vehicle was identified). A research laboratory was set up by FDA to investigate and study Y. enterocolitica and Y. pseudotuberculosis in the human food supply.

Dec. 1981 - Feb. 1982. Y. enterocolitica enteritis in King County, Washington caused by ingestion of tofu, a soybean curd. FDA investigators and researchers determined the source of the infection to be an non-chlorinated water supply. Manufacturing was halted until uncontaminated product was produced.

June 11 to July 21, 1982. Y. enterocolitica outbreak in Arkansas, Tennessee, and Mississippi associated with the consumption of pasteurized milk. FDA personnel participated in the investigation, and presumptively identified the infection source to be externally contaminated milk containers.

A report of Yersinia enterocolitica incidents associated with raw chitterlings may be found in MMWR 39(45):1990 Nov 16

For more information on recent outbreaks see the <u>Morbidity and Mortality Weekly Reports</u> from CDC.

A <u>Loci index for genome Yersinia enterocolitica</u> and <u>Loci index for genome Yersinia pseudotuberculosis</u> are available from GenBank.

Back to Foodborne Bacterial Pathogen List

Salmonella spp

1. Name of the Organism: Salmonella spp.

Salmonella is a rod-shaped, motile bacterium -- nonmotile exceptions *S. gallinarum* and *S. pullorum*--, nonsporeforming and <u>Gram-negative</u>. There is a widespread occurrence in animals, especially in poultry and swine. Environmental sources of the organism include water, soil, insects, factory surfaces, kitchen surfaces, animal feces, raw meats, raw poultry, and raw seafoods, to name only a few.

2. Nature of Acute Disease:

S. *typhi* and the paratyphoid bacteria are normally caused septicemic and produce <u>typhoid</u> or typhoid-like fever in humans. Other forms of salmonellosis generally produce milder symptoms.

3. Nature of Disease:

Acute symptoms -- Nausea, vomiting, abdominal cramps, minal diarrhea, fever, and headache. Chronic consequences -- arthritic symptoms may follow 3-4 weeks after onset of acute symptoms.

Onset time -- 6-48 hours.

Infective dose -- As few as 15-20 cells; depends upon age and health of host, and strain differences among the members of the genus.

Duration of symptoms -- Acute symptoms may last for 1 to 2 days or may be prolonged, again depending on host factors, ingested dose, and strain characteristics.

Cause of disease -- Penetration and passage of Salmonella organisms from gut lumen into epithelium of small intestine where inflammation occurs; there is evidence that an enterotoxin may be produced, perhaps within the enterocyte.

4. Diagnosis of Human Illness:

Serological identification of culture isolated from stool.

5. Associated Foods:

Raw meats, poultry, eggs, milk and dairy products, fish, shrimp, frog legs, yeast, coconut, sauces and salad dressing, cake mixes, cream-filled desserts and toppings, dried gelatin, peanut butter, cocoa, and chocolate.

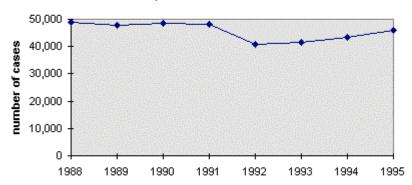

Various Salmonella species have long been isolated from the outside of eggshells. The present situation with *S. enteritidis* is complicated by the presence of the organism inside the egg, in the yolk. This and other information strongly suggest vertical transmission, i.e., deposition of the organism in the yolk by an infected layer hen prior to shell deposition. Foods other than eggs have also caused outbreaks of *S. enteritidis* disease.

6. Relative Frequency of Disease:

It is estimated that from 2 to 4 million cases of salmonellosis occur in the U.S. annually.

The incidence of salmonellosis appears to be rising both in the U.S. and in other industrialized nations. *S. enteritidis* isolations from humans have shown a dramatic rise in the past decade, particularly in the northeast United States (6-fold or more), and the increase in human infections is spreading south and west, with sporadic outbreaks in other regions.

Reported cases Salmonellosis excluding typhoid fever, United States 1988-1995

Summary of Notifiable Diseases, United States MMWR 44(53): 1996 October 25

7. Complications:

S. typhi and S. paratyphi A, B, and C produce typhoid and typhoid-like fever in humans. Various organs may be infected, leading to lesions. The fatality rate of typhoid fever is 10% compared to less than 1% for most forms of salmonellosis. S. dublin has a 15% mortality rate when septicemic in the elderly, and S. enteritidis is demonstrating approximately a 3.6% mortality rate in hospital/nursing home outbreaks, with the elderly being particularly affected.

Salmonella septicemia has been associated with subsequent infection of virtually every organ system.

Postenteritis reactive arthritis and <u>Reiter's syndrome</u> have also been reported to occur generally after 3 weeks. Reactive arthritis may occur with a frequency of about 2% of culture-proven cases. Septic arthritis, subsequent or coincident with septicemia, also occurs and can be difficult to treat.

8. Target Populations:

All age groups are susceptible, but symptoms are most severe in the elderly, infants, and the infirm. <u>AIDS</u> patients suffer salmonellosis frequently (estimated 20-fold more than general population) and suffer from recurrent episodes.

9. Foods Analysis:

Methods have been developed for many foods having prior history of Salmonella contamination. Although conventional culture methods require 5 days for presumptive results, several rapid methods are available which require only 2 days.

10. Selected Outbreaks:

In 1985, low fat and whole milk caused a salmonellosis outbreak involving 16,000 confirmed cases in 6 states from one Chicago dairy. This was the largest outbreak of foodborne salmonellosis in the U.S. FDA inspectors discovered that the pasteurization equipment had been modified to facilitate the running off of raw milk, resulting in the pasteurized milk being contaminated with raw milk under certain conditions. The dairy has subsequently disconnected the cross-linking line. Persons on antibiotic therapy were more apt to be affected in this outbreak.

In August and September, 1985, *S. enteritidis* was isolated from employees and patrons of three restaurants of a chain in Maryland. The outbreak in one restaurant had at least 71 illnesses resulting in 17 hospitalizations. Scrambled eggs from a breakfast bar were epidemiologically implicated in this outbreak and in possibly one other of the three restaurants. The plasmid profiles of isolates from patients all three restaurants matched.

The Centers for Disease Control (CDC) has recorded more than 120 outbreaks of *S. enteritidis* to date, many occurring in restaurants, and some in nursing homes, hospitals and prisons.

In 1984, 186 cases of salmonellosis (S. enteritidis) were reported on 29 flights

to the United States on a single international airline. An estimated 2,747 passengers were affected overall. No specific food item was implicated, but food ordered from the first class menu was strongly associated with disease.

S. enteritidis outbreaks continue to occur in the U.S. (Table 1). The CDC estimates that 75% of those outbreaks are associated with the consumption of raw or inadequately cooked Grade A whole shell eggs. The U.S. Department of Agriculture published Regulations on February 16, 1990, in the Federal Register establishing a mandatory testing program for egg-producing breeder flocks and commercial flocks implicated in causing human illnesses. This testing should lead to a reduction in cases of gastroenteritis caused by the consumption of Grade A whole shell eggs.

Salmonellosis associated with a Thanksgiving Dinner in Nevada in 1995 is reported in MMWR 45(46):1996 Nov 22.

MMWR 45(34):1996 Aug 30 reports on several outbreaks of *Salmonella* enteritidis infection associated with the consumption of raw shell eggs in the United States from 1994 to 1995.

A report of an outbreak of *Salmonella* Serotype Typhimurium infection associated with the consumption of raw ground beef may be found in MMWR 44(49):1995 Dec 15.

MMWR 44(42):1995 Oct 27 reports on an outbreak of Salmonellosis associated with beef jerky in New Mexico in 1995.

The report on the outbreak of Salmonella from commercially prepared ice cream is found in MMWR 43(40):1994 Oct 14.

An outbreak of *S. enteritidis* in homemade ice cream is reported in this MMWR 43(36):1994 Sep 16.

A series of *S. enteritidis* outbreaks in California are summarized in the following MMWR 42(41):1993 Oct 22.

For information on an outbreak of Salmonella Serotype Tennessee in Powdered Milk Products and Infant Formula -- see this MMWR 42(26):1993 Jul 09.

Summaries of Salmonella outbreaks associated with Grade A eggs are reported in MMWR 37(32):1988 Aug 19 and MMWR 39(50):1990 Dec 21.

For more information on recent outbreaks see the Morbidity and Mortality Weekly Reports from CDC.

The CDC provides an informational brochure on preventing <u>Salmonella</u> enteritidis infection.

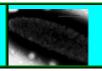

Safe Egg Handling (FDA Consumer Sep - Oct 1998)

Loci index for genome Salmonella enteritidis is available from GenBank.

Back to Foodborne Bacterial Pathogen List

11. Education:

Shigella spp.

1. Name of the Organism:

Shigella spp. (Shigella sonnei, S. boydii, S. flexneri, and S. dysenteriae)

2. Name of Disease:

Shigella are Gram-negative, nonmotile, nonsporeforming rod-shaped bacteria. The illness caused by Shigella (shigellosis) accounts for less than 10% of the reported outbreaks of foodborne illness in this country. Shigella rarely occurs in animals; principally a disease of humans except other primates such as monkeys and chimpanzees. The organism is frequently found in water polluted with human feces.

Shigellosis (bacillary dysentery).

Symptoms -- Abdominal pain; cramps; diarrhea; fever; vomiting; blood, pus, or mucus in stools; tenesmus.

Onset time -- 12 to 50 hours.

Infective dose -- As few as 10 cells depending on age and condition of host. The Shigella spp. are highly infectious agents that are transmitted by the fecal-oral route.

The disease is caused when virulent Shigella organisms attach to, and penetrate, epithelial cells of the intestinal mucosa. After invasion, they multiply intracellularly, and spread to contiguous epitheleal cells resulting in tissue destruction. Some strains produce enterotoxin and Shiga toxin (very much like the verotoxin of *E.* <u>coli</u> O157:H7).

3. Nature of Disease:

4. Diagnosis of Human Illness:

Serological identification of culture isolated from stool.

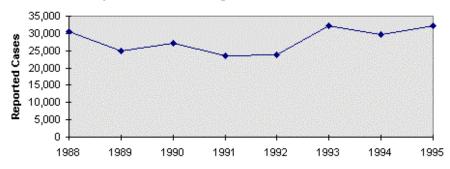

5. Associated Foods:

Salads (potato, tuna, shrimp, macaroni, and chicken), raw vegetables, milk and dairy products, and poultry. Contamination of these foods is usually through the fecal-oral route. Fecally contaminated water and unsanitary handling by food handlers are the most common causes of contamination.

An estimated 300,000 cases of shigellosis occur annually in the U.S. The number attributable to food is unknown, but given the low infectious dose, it is probably substantial.

Reported cases of Shigellosis, United States 1988-1995

Summary of Notifiable Diseases, United States MMWR 44(53): 1996 October 25

7. Complications:

Infections are associated with mucosal ulceration, rectal bleeding, drastic dehydration: fatality may be as high as 10-15% with some strains. Reiter's disease, reactive arthritis, and hemolytic uremic syndrome are possible sequelae that have been reported in the aftermath of shigellosis.

8. Target Populations:

Infants, the elderly, and the infirm are susceptible to the severest symptoms of

disease, but all humans are susceptible to some degree. Shigellosis is a very common malady suffered by individuals with acquired immune deficiency syndrome (AIDS) and <u>AIDS-related complex</u>, as well as non-AIDS homosexual men.

9. Food Analysis:

Organisms are difficult to demonstrate in foods because methods are not developed or are insensitive. A genetic probe to the virulence plasmid has been developed by FDA and is currently under field test. However, the isolation procedures are still poor.

In 1985, a huge outbreak of foodborne shigellosis occurred in Midland-Odessa, Texas, involving perhaps as many as 5,000 persons. The implicated food was chopped, bagged lettuce, prepared in a central location for a Mexican restaurant chain. FDA research subsequently showed that S. sonnei, the isolate from the lettuce, could survive in chopped lettuce under refrigeration, and the lettuce remained fresh and appeared to be quite edible.

In 1985-1986, several outbreaks of shigellosis occurred on college campuses, usually associated with fresh vegetables from the salad bar. Usually an ill food service worker was shown to be the cause.

10. Selected Outbreaks:

In 1987, several very large outbreaks of shigellosis (S. sonnei) occurred involving thousands of persons, but no specific food vector could be proven.

In 1988, numerous individuals contracted shigellosis from food consumed aboard Northwest Airlines flights; food on these flights had been prepared in one central commisary. No specific food item was implicated, but various sandwiches were suspected.

**NOTE - Although all Shigella spp. have been implicated in foodborne outbreaks at some time, S. sonnei is clearly the leading cause of shigellosis from food. The other species are more closely associated with contaminated water. One in particular, S. flexneri, is now thought to be in large part sexually transmitted.

For information on the outbreak of Shigella on a cruise ship, see MMWR 43(35):1994 Sep 09

MMWR 40(25):1991 Jun 28 reports on a Shigella dysenteriae Type 1 outbreak in Guatemala, 1991.

For more information on recent outbreaks see the <u>Morbidity and Mortality</u> <u>Weekly Reports</u> from CDC.

Back to Foodborne Bacterial Pathogen List

Enterotoxigenic *Escherichia* coli

1. Name of the Organism:

Enterotoxigenic Escherichia coli (ETEC)

2. Name of Acute Disease:

3. Nature of Disease:

4. Diagnosis of Human Illness:

5. Associated Foods:

6. Relative Frequency of Disease:

7. Complications:

8. Target Populations:

9. Analysis of Food:

10. Selected Outbreaks:

Currently, there are four recognized classes of enterovirulent *E. coli* (collectively referred to as the EEC group) that cause gastroenteritis in humans. Among these are the enterotoxigenic (ETEC) strains. They comprise a relatively small proportion of the species and have been etiologically associated with diarrheal illness of all age groups from diverse global locations. The organism frequently causes diarrhea in infants in less developed countries and in visitors there from industrialized countries. The etiology of this cholera-like illness has been recognized for about 20 years.

Gastroenteritis is the common name of the illness caused by ETEC, although travelers' diarrhea is a frequent sobriquet.

The most frequent clinical syndrome of infection includes watery diarrhea, abdominal cramps, low-grade fever, nausea and malaise.

Infective dose--Volunteer feeding studies indicate that a relatively large dose (100 million to 10 billion bacteria) of enterotoxigenic *E. coli* is probably necessary to establish colonization of the small intestine, where these organisms proliferate and produce toxins which induce fluid secretion. With high infective dose, diarrhea can be induced within 24 hours. Infants may require fewer organisms for infection to be established.

During the acute phase of infection, large numbers of enterotoxigenic cells are excreted in feces. These strains are differentiated from nontoxigenic *E. coli* present in the bowel by a variety of in vitro immunochemical, tissue culture, or gene probe tests designed to detect either the toxins or genes that encode for these toxins. The diagnosis can be completed in about 3 days.

ETEC is not considered a serious foodborne disease hazard in countries having high sanitary standards and practices. Contamination of water with human sewage may lead to contamination of foods. Infected food handlers may also contaminate foods. These organisms are infrequently isolated from dairy products such as semi-soft cheeses.

Only four outbreaks in the U.S. have been documented, one resulting from consumption of water contaminated with human sewage, another from consumption of Mexican food prepared by an infected food handler. In two others, one in a hospital cafeteria and one aboard a cruise ship, food was the probable cause. The disease among travelers to foreign countries, however, is common.

The disease is usually self-limiting. In infants or debilitated elderly persons, appropriate electrolyte replacement therapy may be necessary.

Infants and travelers to underdeveloped countries are most at-risk of infection.

With the availability of a gene probe method, foods can be analyzed directly for the presence of enterotoxigenic *E. coli*, and the analysis can be completed in about 3 days. Alternative methods which involve enrichment and plating of samples for isolation of *E. coli* and their subsequent confirmation as toxigenic strains by conventional toxin assays may take at least 7 days.

In the last decade, four major common-source outbreaks of ETEC gastroenteritis occurred in the U.S. In late 1975 one-third of the passengers on two successive cruises of a Miami-based ship experienced diarrheal illness. A CDC investigation found ETEC to be the cause, presumably linked to

consumption of crabmeat cocktail. In early 1980, 415 persons eating at a Mexican restaurant experienced diarrhea. The source of the causative organism was an ill food handler. In 1981, 282 of 3,000 personnel at a Texas hospital acquired ETEC gastroenteritis after eating in the hospital cafeteria. CDC identified no single food.

Outbreaks of ETEC in Rhode Island and New Hampshire are reported in this MMWR 43(5):1994 Feb 11.

For more information on recent outbreaks see the <u>Morbidity and Mortality Weekly Reports</u> from CDC.

Back to Foodborne Bacterial Pathogen List

Enteropathogenic *Escherichia* coli

1. Name of the Organism:

Enteropathogenic Escherichia coli (EPEC) Currently, there are four recognized classes of enterovirulent *E. coli* (collectively referred to as the EEC group) that cause gastroenteritis in humans. Among these are the enteropathogenic (EPEC) strains. EPEC are defined as *E. coli* belonging to serogroups epidemiologically implicated as pathogens but whose virulence mechanism is unrelated to the excretion of typical *E. coli* enterotoxins. *E. coli* are Gram-negative, rod-shaped bacteria belonging the family Enterobacteriaceae. Source(s) and prevalence of EPEC are controversial because foodborne outbreaks are sporadic. Humans, bovines, and swine can be infected, and the latter often serve as common experimental animal models. *E. coli* are present in the normal gut flora of these mammals. The proportion of pathogenic to nonpathogenic strains, although the subject of intense research, is unknown.

2. Name of Acute Disease:

3. Nature of Disease:

Infantile diarrhea is the name of the disease usually associated with EPEC.

EPEC cause either a watery or bloody diarrhea, the former associated with the attachment to, and physical alteration of, the integrity of the intestine. Bloody diarrhea is associated with attachment and an acute tissue-destructive process, perhaps caused by a toxin similar to that of <u>Shigella dysenteriae</u>, also called verotoxin. In most of these strains the shiga-like toxin is cell-associated rather than excreted.

Infective dose -- EPEC are highly infectious for infants and the dose is presumably very low. In the few documented cases of adult diseases, the dose is presumably similar to other colonizers (greater than 10⁶ total dose).

4. Diagnosis of Human Illness:

5. Associated Foods:

6. Relative Frequency of Disease:

7. Usual Course of Disease and Some Complications:

8. Target Populations:

The distinction of EPEC from other groups of pathogenic *E. coli* isolated from patients' stools involves serological and cell culture assays. Serotyping, although useful, is not strict for EPEC.

Common foods implicated in EPEC outbreaks are raw beef and chicken, although any food exposed to fecal contamination is strongly suspect.

Outbreaks of EPEC are sporadic. Incidence varies on a worldwide basis; countries with poor sanitation practices have the most frequent outbreaks.

Occasionally, diarrhea in infants is prolonged, leading to dehydration, electrolyte imbalance and death (50% mortality rates have been reported in third world countries).

EPEC outbreaks most often affect infants, especially those that are bottle fed, suggesting that contaminated water is often used to rehydrate infant formulae in underdeveloped countries.

9. Analysis of Foods:

The isolation and identification of *E. coli* in foods follows standard enrichment and biochemical procedures. Serotyping of isolates to distinguish EPEC is laborious and requires high quality, specific antisera, and technical expertise. The total analysis may require from 7 to 14 days.

10. Selected Outbreaks:

Sporadic outbreaks of EPEC diarrhea have occurred for half a century in infant nurseries, presumably derived from the hospital environment or contaminated infant formula. Common-source outbreaks of EPEC diarrhea involving healthy young adults were reported in the late 1960s. Presumably a large inoculum was ingested.

For more information on recent outbreaks see the <u>Morbidity and Mortality</u> <u>Weekly Reports</u> from CDC.

Back to Foodborne Bacterial Pathogen List

Escherichia coli O157:H7

1. Name of the Organism:

Escherichia coli O157:H7 (enterohemorrhagic E. coli or EHEC) Currently, there are four recognized classes of enterovirulent *E. coli* (collectively referred to as the EEC group) that cause gastroenteritis in humans. Among these is the enterohemorrhagic (EHEC) strain designated *E. coli* O157:H7. *E. coli* is a normal inhabitant of the intestines of all animals, including humans. When aerobic culture methods are used, *E. coli* is the dominant species found in feces. Normally *E. coli* serves a useful function in the body by suppressing the growth of harmful bacterial species and by synthesizing appreciable amounts of vitamins. A minority of *E. coli* strains are capable of causing human illness by several different mechanisms. *E. coli* serotype O157:H7 is a rare variety of *E. coli* that produces large quantities of one or more related, potent toxins that cause severe damage to the lining of the intestine. These toxins [verotoxin (VT), shiga-like toxin] are closely related or identical to the toxin produced by *Shigella dysenteriae*.

2. Name of Acute Disease:

3. Nature of Disease:

Hemorrhagic colitis is the name of the acute disease caused by *E. coli* O157:H7.

The illness is characterized by severe cramping (abdominal pain) and diarrhea that is initially watery but becomes grossly bloody. Occasionally vomiting occurs. Fever is either low-grade or absent. The illness is usually self-limited and lasts for an average of 8 days. Some individuals exhibit watery diarrhea only.

Infective dose -- Unknown, but from a compilation of outbreak data, including the organism's ability to be passed person-to-person in the day-care setting and nursing homes, the dose may be similar to that of *Shigella spp.* (10 organisms).

4. Diagnosis of Human Illness:

5. Associated Foods:

6. Relative Frequency

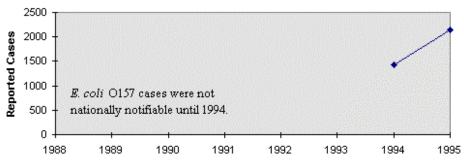

of Disease:

Hemorrhagic colitis is diagnosed by isolation of *E. coli* of serotype O157:H7 or other verotoxin-producing *E. coli* from diarrheal stools. Alternatively, the stools can be tested directly for the presence of verotoxin. Confirmation can be obtained by isolation of *E. coli* of the same serotype from the incriminated food.

Undercooked or raw hamburger (ground beef) has been implicated in nearly all documented outbreaks and in other sporadic cases. Raw milk was the vehicle in a school outbreak in Canada. These are the only two demonstrated food causes of disease, but other meats may contain *E. coli* O157:H7.

Hemorrhagic colitis infections are not too common, but this is probably not reflective of the true frequency. In the Pacific Northwest, *E. coli* O157:H7 is thought to be second only to Salmonella as a cause of bacterial diarrhea. Because of the unmistakable symptoms of profuse, visible blood in severe cases, those victims probably seek medical attention, but less severe cases are probably more numerous.

Reported Cases of E. coli 0157, United States 1994-1995

Summary of Notifiable Diseases, United States MMWR 44(53): 1996 October 25

7. Usual Course of Disease and Some Complications:

Some victims, particularly the very young, have developed the hemolytic uremic syndrome (HUS), characterized by renal failure and hemolytic anemia. From 0 to 15% of hemorrhagic colitis victims may develop HUS. The disease can lead to permanent loss of kidney function.

In the elderly, HUS, plus two other symptoms, fever and neurologic symptoms, constitutes thrombotic <u>thrombocytopenic purpura</u> (TTP). This illness can have a mortality rate in the elderly as high as 50%.

8. Target Populations:

All people are believed to be susceptible to hemorrhagic colitis, but larger outbreaks have occurred in institutional settings.

9. Analysis of Foods:

E. coli 0157:H7 will form colonies on agar media that are selective for *E. coli*. However, the high temperature growth procedure normally performed to eliminate background organisms before plating cannot be used because of the inability of these organisms to grow at temperatures of 44.0 - 45.5°C that support the growth of most *E. coli*. The use of DNA probes to detect genes encoding for the production of verotoxins (VT1 and VT2) is the most sensitive method devised.

10. Selected Outbreaks:

Three outbreaks occurred in 1982. Two of them, one in Michigan and one in Oregon, involved hamburgers from a national fast-food chain. The third occurred in a home for the aged in Ottawa, Ontario; club sandwiches were implicated, and 19 people died. More recently, several outbreaks in nursing homes and a day-care center have been investigated. Two large outbreaks occurred in 1984, one in 1985, three in 1986. Larger outbreaks have occurred in the Northwest U.S. and Canada.

In October-November, 1986, an outbreak of hemorrhagic colitis caused by *E. coli* O157:H7 occurred in Walla Walla, WA. Thirty-seven people, aged 11 months to 78 years developed diarrhea caused by the organism. All isolates from patients (14) had a unique plasmid profile and produced Shiga-like toxin II. In addition to diarrhea, 36 persons reported grossly bloody stools and 36 of the 37 reported abdominal cramps. Seventeen patients were hospitalized. One patient developed HUS (4 years old) and three developed TTP (70, 78, and 78 years old). Two patients with TTP died. Ground beef was the implicated food vehicle.

An excellent summary of nine *E. coli* O157:H7 outbreaks appeared in the Annals of Internal Medicine, 1 November, 1988, pp. 705-712.

There was a recall of frozen hamburger underway (12 Aug 1997). For more information, see the <u>USDA announcement</u> and <u>follow-up announcement</u> (15 Aug 1997) on the U.S. Department of Agriculture web site concerning the recall of Hudson frozen ground beef.

The Centers for Disease Control and Prevention have reported on the above outbreak in <u>preliminary (MMWR 45(44):975, 1996 November 8)</u> and in <u>updated (MMWR 46(1):4-8, 1997 January 10)</u> form.

The FDA has issued on 31 October 1996 a press release concerning an outbreak of

E. coli O157:H7 associated with Odwalla brand apple juice products.

A non-food related outbreak of *E. coli* O157:H7 is reported in MMWR 45(21):1996 May 31. While, the source of the outbreak is thought to be waterborne, the article is linked to this chapter to provide updated reference information on enterohemorrhagic *E. coli*.

MMWR 45(12):1996 Mar 29 reports on an outbreak of O157:H7 that occurred in Georgia and Tennessee in June of 1995.

A community outbreak of hemolytic uremic syndrome attributable to *Escherichia coli* O111:NM in southern Australia in 1995 is reported in MMWR 44(29):1995 Jul 28.

A report on enhanced detection of sporadic *E. coli* O157:H7 infections in New Jersey and on an *E. coli* O157:H7 outbreak at a summer camp are in MMWR 44(22): 1995 Jun 9.

An outbreak of *E. coli* O157:H7 in Washington and California associated with drycured salami is reported in MMWR 44(9):1995 Mar 10.

Information concerning an outbreak that occurred because of home-cooked hamburger can be found in this MMWR 43(12):1994 Apr 01.

MMWR 43(10):1994 Mar 18 reports on laboratory screening for *E. coli* O157 in Connecticut.

The outbreak of EHEC in the western states of the US is reported in preliminary form in this MMWR 42(4):1993 Feb 5, and in updated form in this MMWR 42(14):1993 Apr 16.

An outbreak of *E. coli* O157 in 1990 in North Dakota is reported in the MMWR 40(16):1991 Apr 26.

The Centers for Disease Control and Prevention has reissued the <u>5 November 1982</u> MMWR report that was the first to describe the diarrheal illness of *E. coli* O157:H7. This reissue is a part of the commemoration of CDC's 50th anniversary.

For more information on recent outbreaks see the Morbidity and Mortality Weekly Reports from CDC.

<u>USDA Urges Consumers To Use Food Thermometer When Cooking Ground Beef</u> Patties (Aug 11 1998)

The CDC has an information brochure on preventing <u>Escherichia coli O157:H7</u> infections.

12. Other Resources:

Dr. Feng of FDA/CFSAN has written a monograph on *E. coli* O157:H7 which appeared in the CDC journal <u>Emerging Infectious Diseases Vol. 1 No. 2, April-June</u> 1995.

Back to Foodborne Bacterial Pathogen List

Enteroinvasive Escherichia coli

Name of the Organism:

Enteroinvasive Escherichia coli or (EIEC) Currently, there are four recognized classes of enterovirulent *E. coli* (collectively referred to as the EEC group) that cause gastroenteritis in humans. *E. coli* is part of the normal intestinal flora of humans and other primates. A minority of *E. coli* strains are capable of causing human illness by several different mechanisms. Among these are the enteroinvasive (EIEC) strains. It is unknown what foods may harbor these pathogenic enteroinvasive (EIEC) strains responsible for a form of bacillary dysentery.

2. Name of Disease:

Enteroinvasive *E. coli* (EIEC) may produce an illness known as bacillary dysentery. The EIEC strains responsible for this syndrome are closely related to *Shigella spp*.

3. Nature of the Disease:

Following the ingestion of EIEC, the organisms invade the epithelial cells of the intestine, resulting in a mild form of dysentery, often mistaken for dysentery caused by *Shigella* species. The illness is characterized by the appearance of blood and mucus in the stools of infected individuals.

Infective dose -- The infectious dose of EIEC is thought to be as few as 10 organisms (same as *Shigella*).

4. Diagnosis of Human Illness:

The culturing of the organism from the stools of infected individuals and the demonstration of invasiveness of isolates in tissue culture or in a suitable animal model is necessary to diagnose dysentery caused by this organism.

More recently, genetic probes for the invasiveness genes of both EIEC and *Shigella spp.* have been developed.

5. Associated Foods:

It is currently unknown what foods may harbor EIEC, but any food contaminated with human feces from an ill individual, either directly or via contaminated water, could cause disease in others. Outbreaks have been associated with hamburger meat and unpasteurized milk.

6. Relative Frequency of Disease:

One major foodborne outbreak attributed to enteroinvasive *E. coli* in the U.S. occurred in 1973. It was due to the consumption of imported cheese from France. The disease caused by EIEC is uncommon, but it may be confused with shigellosis and its prevalence may be underestimated.

7. The Usual Course of Disease and Some Complications:

Dysentery caused by EIEC usually occurs within 12 to 72 hours following the ingestion of contaminated food. Abdominal cramps, diarrhea, vomiting, fever, chills, and a generalized malaise characterize the illness. Dysentery caused by this organism is generally self-limiting with no known complications. A common sequelus associated with infection, especially in pediatric cases, is hemolytics.nemic syndrome (HUS).

8. Target Populations:

All people are subject to infection by this organism.

9. Analysis of Foods:

Foods are examined as are stool cultures. Detection of this organism in foods is extremely difficult because undetectable levels may cause illness. It is estimated that the ingestion of as few as 10 organisms may result in dysentery.

10. Selected Outbreaks:

Several outbreaks in the U.S. have been attributed to this organism. One outbreak occurred in 1973 and was due to the consumption of imported cheese. More recently, a cruise ship outbreak was attributed to potato salad, and an outbreak occurred in a home for the mentally retarded where subsequent person-to-person transmission occurred.

For more information on recent outbreaks see the <u>Morbidity and Mortality Weekly Reports</u> from CDC.

Vibrio cholerae Serogroup O1

1. Name of the Organism: *Vibrio cholerae* Serogroup Ol

This bacterium is responsible for Asiatic or epidemic <u>cholera</u>. No major outbreaks of this disease have occurred in the United States since 1911. However, sporadic cases occurred between 1973 and 1991, suggesting the possible reintroduction of the organism into the U.S. marine and estuarine environment. The cases between 1973 and 1991 were associated with the consumption of raw shellfish or of shellfish either improperly cooked or recontaminated after proper cooking. Environmental studies have demonstrated that strains of this organism may be found in the temperate estuarine and marine coastal areas surrounding the United States.

In 1991 outbreaks of cholera in Peru quickly grew to epidemic proportions and spread to other South American and Central American countries, including Mexico. Over 340,000 cases and 3,600 deaths have been reported in the Western Hemisphere since January 1991. However, only 24 cases of cholera have been reported in the United States. The U.S. cases were brought into the country by travelers returning from South America, or were associated with illegally smuggled, temperature-abused crustaceans.

2. Name of Acute Disease:

Cholera is the name of the infection caused by V. cholerae.

Symptoms of Asiatic cholera may vary from a mild, watery diarrhea to an acute diarrhea, with characteristic rice water stools. Onset of the illness is generally sudden, with incubation periods varying from 6 hours to 5 days. Abdominal cramps, nausea, vomiting, dehydration, and shock; after severe fluid and electrolyte loss, death may occur. Illness is caused by the ingestion of viable bacteria, which attach to the small intestine and produce cholera toxin. The production of cholera toxin by the attached bacteria results in the watery diarrhea associated with this illness.

3. Nature of the Disease:

Infective dose -- Human volunteer feeding studies utilizing healthy individuals have demonstrated that approximately one million organisms must be ingested to cause illness. <u>Antacid</u> consumption markedly lowers the infective dose.

4. Diagnosis of Human Illness:

Cholera can be confirmed only by the isolation of the causative organism from the diarrheic stools of infected individuals.

5. Foods in which it Occurs:

Cholera is generally a disease spread by poor <u>sanitation</u>, resulting in contaminated water supplies. This is clearly the main mechanism for the spread of cholera in poor communities in South America. The excellent sanitation facilities in the U.S. are responsible for the near eradication of epidemic cholera. Sporadic cases occur when shellfish harvested from fecally polluted coastal waters are consumed raw. Cholera may also be transmitted by shellfish harvested from nonpolluted waters since *V. cholerae* O1 is part of the autochthonous microbiota of these waters.

6. Relative Frequency of Disease:

Fewer than 80 proven cases of cholera have been reported in the U.S. since 1973. Most of these cases were detected only after epidemiological investigation. Probably more sporadic cases have occurred, but have gone undiagnosed or unreported.

7. The Usual Course of Disease and Some Complications:

Individuals infected with cholera require rehydration either intravenously or orally with a solution containing sodium chloride, sodium bicarbonate, potassium chloride, and dextrose (glucose). The illness is generally self-limiting. Antibiotics such as tetracycline have been demonstrated to shorten the course of the illness. Death occurs from dehydration and loss of essential electrolytes. Medical treatment to prevent dehydration prevents all complications.

8. Target Populations:

All people are believed to be susceptible to infection, but individuals with damaged or undeveloped immunity, reduced <u>gastric acidity</u>, or malnutrition may suffer more severe forms of the illness.

9. Analysis of Foods:

V. cholerae serogroup O1 may be recovered from foods by methods similar to those used for recovering the organism from the feces of infected individuals. Pathogenic and non- pathogenic forms of the organism exist, so all food isolates must be tested for the production of cholera enterotoxin.

An incident of cholera in Indiana from imported food is reported in MMWR 44(20):1995 May 20.

See MMWR 44(11):1995 Mar 24 for an updated report on *Vibrio cholerae* O1 in the Western Hemisphere 1991-1994 and on *V. cholerae* O139 in Asia. 1994.

Surveillance for cholera in Cochabamba Department, Bolivia is discussed in in this MMWR 42(33):1993 Aug 27.

The cholera outbreak in Burundi and Zimbabwe is detailed in the following MMWR 42(21):1993 Jun 04.

MMWR 40(49):1991 Dec 13 reports on a cholera outbreak associated with imported coconut milk.

10. Selected Outbreaks:

A report of a cholera incident in New York is found in MMWR 40(30):1991 Aug 01.

Similar incidents in New Jersey and Florida are reported in MMWR 40(17):1991 May 03.

A case of importation of cholera from Peru to the United States is detailed in MMWR 40(15):1991 Apr 19.

The cholera outbreak in Peru is reported on in MMWR:40(6):1991 Feb 15, and the update of the South American endemic is in MMWR 40(13):1991 Apr 5.

For more information on recent outbreaks see the <u>Morbidity and Mortality Weekly Reports</u> from CDC.

The CDC has a brochure on the prevention of cholera in English in Spanish in Portuguese

Vibrio cholerae Serogroup Non-O1

1. Name of the Organism: *Vibrio cholerae* Serogroup Non-Ol

2. Name of Acute Disease:

3. Nature of the Disease:

- 4. Diagnosis of Human Illness:
- 5. Foods in which it Occurs:
- 6. Relative Frequency of Disease:
- 7. The Usual Course of Disease and Some Complications:
- 8. Target Populations:
- 9. Analysis of Foods:

This bacterium infects only humans and other primates. It is related to *V. cholerae* Serogroup O1, the organism that causes Asiatic or epidemic cholera, but causes a disease less severe than cholera. Both pathogenic and nonpathogenic strains of the organism are normal inhabitants of marine and estuarine environments of the United States. This organism has been referred to as non-cholera vibrio (NCV) and nonagglutinable vibrio (NAG) in the past.

Non-OI *V. cholerae* gastroenteritis is the name associated with this illness.

Diarrhea, abdominal cramps, and fever are the predominant symptoms associated with this illness, with vomiting and nausea occurring in approximately 25% of infected individuals. Approximately 25% of infected individuals will have blood and mucus in their stools. Diarrhea may, in some cases, be quite severe, lasting 6-7 days. Diarrhea will usually occur within 48 hours following ingestion of the organism. It is unknown how the organism causes the illness, although an enterotoxin is suspected as well as an invasive mechanism. Disease is caused when the organism attaches itself to the small intestine of infected individuals and perhaps subsequently invades.

Infective dose -- It is suspected that large numbers (more than one million) of the organism must be ingested to cause illness.

Diagnosis of a *V. cholerae* non-Ol infection is made by culturing the organism from an individual's diarrheic stool.

Shellfish harvested from U.S. coastal waters frequently contain *V. cholerae* serogroup non-Ol. Consumption of raw, improperly cooked or cooked, recontaminated shellfish may lead to infection.

No major outbreaks of diarrhea have been attributed to this organism. Sporadic cases occur frequently mainly along the coasts of the U.S., and are usually associated with the consumption of raw oysters during the warmer months.

Diarrhea resulting from ingestion of the organism usually lasts 7 days and is self-limiting. Antibiotics such as tetracycline shorten the severity and duration of the illness. Septicemia (bacteria gaining entry into the blood stream and multiplying therein) can occur. This complication is associated with individuals with cirrhosis of the liver, or who are immunosuppressed, but this is relatively rare. FDA has warned individuals with liver disease to refrain from consuming raw or improperly cooked shellfish.

All individuals who consume raw shellfish are susceptible to diarrhea caused by this organism. Cirrhotic or immunosuppressed individuals may develop severe complications such as septicemia.

Methods used to isolate this organism from foods are similar to those used with diarrheic stools. Because many food isolates

	are nonpathogenic, pathogenicity of all food isolates must be demonstrated. All virulence mechanisms of this group have not been elucidated; therefore, pathogenicity testing must be performed in suitable animal models.
10. Selected Outbreaks:	Sporadic cases continue to occur all year, increasing in frequency during the warmer months.
	An update report from CDC on <i>Vibrio cholerae</i> O139 in Asia may be found in MMWR 44(11):1995 Mar 24.
	See MMWR 42(26):1993 Jul 09 for a report on the new O139 Non-O1 Vibrio cholerae (Bengal).
	For more information on recent outbreaks see the Morbidity and Mortality Weekly Reports from CDC.

Vibrio parahaemolyticus

1. Name of the Organism:

Vibrio parahaemolyticus (and other marine Vibrio spp.**)

- 2. Name of Acute Disease:
- 3. Nature of the Disease:
- 4. Diagnosis of Human Illness:
- 5. Associated Foods:
- 6. Relative Frequency of Disease:
- 7. The Usual Course of the Disease:
- 8. Target populations:
- 9. Analysis of Foods:
- 10. Selected Outbreaks:

This bacterium is frequently isolated from the estuarine and marine environment of the United States. Both pathogenic and non-pathogenic forms of the organism can be isolated from marine and estuarine environments and from fish and shellfish dwelling in these environments.

V. parahaemolyticus-associated gastroenteritis is the name of the infection caused by this organism.

Diarrhea, abdominal cramps, nausea, vomiting, headache, fever, and chills may be associated with infections caused by this organism. The illness is usually mild or moderate, although some cases may require hospitalization. The median duration of the illness is 2.5 days. The incubation period is 4-96 hours after the ingestion of the organism, with a mean of 15 hours. Disease is caused when the organism attaches itself to an individuals' small intestine and excretes an as yet unidentified toxin.

Infective dose -- A total dose of greater than one million organisms may cause disease; this is markedly lowered by <u>antacids</u> (or presumably by food with buffering capability).

Diagnosis of gastroenteritis caused by this organism is made by culturing the organism from the diarrheic stools of an individual.

Infections with this organism have been associated with the consumption of raw, improperly cooked, or cooked, recontaminated fish and shellfish. A correlation exists between the probability of infection and warmer months of the year. Improper refrigeration of seafoods contaminated with this organism will allow its proliferation, which increases the possibility of infection.

Major outbreaks have occurred in the U.S. during the warmer months of the year. Sporadic cases occur frequently along all coasts of the U.S.

Diarrhea caused by this organism is usually self-limiting, with few cases requiring hospitalization and/or antibiotic treatment.

All individuals who consume raw or improperly cooked fish and shellfish are susceptible to infection by this organism.

Methods used to isolate this organism from foods are similar to those used with diarrheic stools. Because many food isolates are nonpathogenic, pathogenicity of all food isolates must be demonstrated. Although the demonstration of the Kanagawa hemolysin was long considered indicative of pathogenicity, this is now uncertain.

Sporadic outbreaks of gastroenteritis caused by this organism have occurred in the U.S. and cases are more common during the warmer months. It is very common in Japan, where large outbreaks occur with regularity.

**OTHER MARINE VIBRIOS IMPLICATED IN FOODBORNE DISEASE:

Several other marine vibrios have been implicated in human disease. Some may cause wound or ear infections, and others, gastroenteritis. The amount of evidence for certain of these organisms as being causative of human gastroenteritis is small. Nonetheless, several have been isolated from human feces from diarrhea patients from which no other pathogens could be isolated. Methods for recovery of these organisms from foods are similar to those used for recovery of *V. parahaemolyticus*. The species implicated in human disease include:

Vibrio alginolyticus Vibrio furnissii

Vibrio carchariae Vibrio hollisae

Vibrio cincinnatiensis Vibrio metschnikovii

Vibrio damsela Vibrio mimicus

Vibrio fluvialis

For more information on recent outbreaks see the Morbidity and Mortality Weekly Reports from CDC.

11. Other Resources:

A <u>Loci index for genome *Vibrio parahaemolyticus*</u> is available from GenBank.

Vibrio vulnificus

- **1. Name of the Organism:** *Vibrio vulnificus*
- 2. Name of the Acute Disease:

3. Nature of the Disease:

- 4. Diagnosis of Human Illness:
- 5 .Associated Foods:

6. Relative Frequency of Disease:

7. The Usual Course of Disease and Some Complications:

This bacterium infects only humans and other primates. It has been isolated from a wide range of environmental sources, including water, sediment, plankton, and shellfish (oysters, clams, and crabs) and a variety of locations, including the Gulf of Mexico, the Atlantic Coast as far north as Cape Cod, and the entire U.S. west coast. Cases of illness have also been associated with brackish lakes in New Mexico and Oklahoma.

This organism causes wound infections, gastroenteritis, or a syndrome known as "primary septicemia."

Wound infections result either from contaminating an open wound with sea water harboring the organism, or by lacerating part of the body on coral, fish, etc., followed by contamination with the organism. The ingestion of *V. vulnificus* by healthy individuals can result in gastroenteritis. The "primary septicemia" form of the disease follows consumption of raw seafood containing the organism by individuals with underlying chronic disease, particularly liver disease (see below). In these individuals, the microorganism enters the blood stream, resulting in septic shock, rapidly followed by death in many cases (about 50%). Over 70% of infected individuals have distinctive bulbous skin lesions.

Infective dose -- The infective dose for gastrointestinal symptoms in healthy individuals is unknown but for predisposed persons, septicemia can presumably occur with doses of less than 100 total organisms.

The culturing of the organism from wounds, diarrheic stools, or blood is diagnostic of this illness.

This organism has been isolated from oysters, clams, and crabs. Consumption of these products raw or recontaminated may result in illness.

No major outbreaks of illness have been attributed to this organism. Sporadic cases occur frequently, becoming more prevalent during the warmer months.

In a survey of cases of *V. vulnificus* infections in Florida from 1981 to 1987, Klontz et al. (Annals of Internal Medicine 109:318-23;1988) reported that 38 cases of primary septicemia (ingestion), 17 wound infections, and 7 cases gastroenteritis were associated with the organism. Mortality from infection varied from 55% for primary septicemia cases, to 24% with wound infections, to no deaths associated with gastroenteritis. Raw oyster consumption was a common feature of primary septicemia and gastroenteritis, and liver disease was a feature of primary septicemia.

In healthy individuals, gastroenteritis usually occurs within 16 hours of ingesting the organism. Ingestion of the organism by individuals with some type of chronic underlying disease [such as <u>diabetes</u>, <u>cirrhosis</u>, leukemia, lung carcinoma, acquired immune deficiency syndrome (AIDS), AIDS- related complex (ARC), or asthma requiring the use of steroids] may cause the

8. Target Populations:	"primary septicemia" form of illness. The mortality rate for individuals with this form of the disease is over 50%. All individuals who consume foods contaminated with this organism are susceptible to gastroenteritis. Individuals with diabetes, cirrhosis, or leukemia, or those who take immunosuppressive drugs or steroids are particularly susceptible to primary septicemia. These individuals should be strongly advised not to consume raw or inadequately cooked seafood, as should AIDS/ARC patients.
9. Analysis of Foods:	Methods used to isolate this organism from foods are similar to those used with diarrheic stools. To date, all food isolates of this organism have been pathogenic in animal models. FDA has a genetic probe for <i>V. vulnificus</i> ; its target is a cytotoxin gene that appears not to correlate with the organism's virulence.
10. Selected Outbreaks:	Sporadic cases continue to occur all year, increasing in frequency during the warmer months.
	MMWR 45(28):1996 Jul 26 reports on three incidents of <i>V. vulnificus</i> infection in Los Angeles, California.
	A multi-year summary of <i>V. vulnificus</i> incidents associated with the consumption of raw oysters is reported in <u>MMWR</u> <u>42(21):1993 Jun 04</u>
	For more information on recent outbreaks see the Morbidity and Mortality Weekly Reports from CDC.
11. Education:	More information for consumers of raw shellfish is available in the FDA brochure <u>If You Eat Raw Oysters</u> , <u>You Need to Know</u> .

Plesiomonas shigelloides

1. Name of the Organism:

Plesiomonas shigelloides

2. Name of Acute Disease:

3. Nature of Disease:

4. Diagnosis of Human Illness:

5. Associated Foods:

6. Frequency of Disease:

7. Usual Course of Disease and Some Complications:

8. Target Populations:

9. Food Analysis:

This is a <u>Gram-negative</u>, rod-shaped bacterium that has been isolated from freshwater, freshwater fish, and shellfish and from many types of animals including cattle, goats, swine, cats, dogs, monkeys, vultures, snakes, and toads.

Most human *P. shigelloides* infections are suspected to be waterborne. The organism may be present in unsanitary water that has been used as drinking water, recreational water, or water used to rinse foods that are consumed without cooking or heating. The ingested *P. shigelloides* organism does not always cause illness in the host animal but may reside temporarily as a transient, noninfectious member of the intestinal flora. It has been isolated from the stools of patients with diarrhea, but is also sometimes isolated from healthy individuals (0.2-3.2% of population).

It cannot yet be considered a definite cause of human disease, although its association with human diarrhea and the virulence factors it demonstrates make it a prime candidate.

Gastroenteritis is the disease with which *P. shigelloides* has been implicated.

P. shigelloides gastroenteritis is usually a mild self-limiting disease with fever, chills, abdominal pain, nausea, diarrhea, or vomiting; symptoms may begin 20-24 hours after consumption of contaminated food or water; diarrhea is watery, non-mucoid, and non-bloody; in severe cases, diarrhea may be greenish-yellow, foamy, and blood tinged; duration of illness in healthy people may be 1-7 days.

The infectious dose is presumed to be quite high, at least greater than one million organisms.

The pathogenesis of *P. shigelloides* infection is not known. The organism is suspected of being toxigenic and invasive. Its significance as an enteric (intestinal) pathogen is presumed because of its predominant isolation from stools of patients with diarrhea. It is identified by common bacteriological analysis, serotyping, and antibiotic sensitivity testing.

Most *P. shigelloides* infections occur in the summer months and correlate with environmental contamination of freshwater (rivers, streams, ponds, etc.). The usual route of transmission of the organism in sporadic or epidemic cases is by ingestion of contaminated water or raw shellfish.

Most *P. shigelloides* strains associated with human gastrointestinal disease have been from stools of diarrheic patients living in tropical and subtropical areas. Such infections are rarely reported in the U.S. or Europe because of the self-limiting nature of the disease.

*P. shigelloid*es infection may cause diarrhea of 1-2 days duration in healthy adults. However, there may be high fever and chills and protracted dysenteric symptoms in infants and children under 15 years of age. Extra- intestinal complications (septicemia and death) may occur in people who are immunocompromised or seriously ill with cancer, blood disorders, or hepatobiliary disease.

All people may be susceptible to infection. Infants, children and chronically ill people are more likely to experience protracted illness and complications.

P. shigelloides may be recovered from food and water by methods similar to those used for stool analysis. The keys to recovery in all cases are selective agars that enhance the survival and growth of these bacteria over the growth of the background microflora. Identification following recovery may be completed in 12-24 hours.

10. Selected Outbreaks:

Gastrointestinal illness in healthy people caused by *P. shigelloides* infection may be so mild that they do not seek medical treatment. Its rate of occurrence in the U.S. is unknown. It may be included in the group of diarrheal diseases "of unknown etiology" which are treated with and respond to broad spectrum antibiotics.

Most cases reported in the United States involve individuals with preexisting health problems such as cancer, sickle cell anemia, <u>immunoincompetence</u>, the aged, and the very young, who develop complications.

A case cluster occurred in North Carolina in November, 1980, following an oyster roast. Thirty-six out of 150 people who had eaten roasted oysters experienced nausea, chills, fever, vomiting, diarrhea, and abdominal pain beginning 2 days after the roast. The average duration of these symptoms was 2 days. *P. shigelloides* was recovered from oyster samples and patient stools.

A non-food related outbreak of *P. shigelloides* is reported in MMWR 38(36):1989 Sep 15.

For more information on recent outbreaks see the <u>Morbidity and Mortality</u> <u>Weekly Reports</u> from CDC.

Gram Positive Rods

The gram positive rods and cocci that will be covered in this module are: Bacillus cereus; Listeria monocytogenes; Clostridium perfringens; Clostridium botulinum; Staphylococcus, Streptococcus, Aeromonas hydrophila, Miscellaneous enterics

Bacillus cereus and other Bacillus spp.

1. Name of the Organism: *Bacillus cereus* and other *Bacillus* spp.

r *Bacillu*s

2. Name of Illness:

3. Nature of Illness:

4. Diagnosis of Human Illness:

5. Foods Incriminated:

Bacillus cereus is a Gram-positive, facultatively aerobic sporeformer whose cells are large rods and whose spores do not swell the sporangium. These and other characteristics, including biochemical features, are used to differentiate and confirm the presence B. cereus, although these characteristics are shared with B. cereus var. mycoides, B. thuringiensis and B. anthracis. Differentiation of these organisms depends upon determination of motility (most B. cereus are motile), presence of toxin crystals (B. thuringiensis), hemolytic activity (B. cereus and others are beta hemolytic whereas B. anthracis is usually nonhemolytic), and rhizoid growth which is characteristic of B. cereus var. mycoides.

B. cereus food poisoning is the general description, although two recognized types of illness are caused by two distinct metabolites. A large molecular weight protein causes the diarrheal type of illness, while the vomiting (emetic) type of illness is believed to be caused by a low molecular weight, heat-stable peptide.

The symptoms of *B. cereus* diarrheal type food poisoning mimic those of <u>Clostridium perfringens</u> food poisoning. The onset of watery diarrhea, abdominal cramps, and pain occurs 6-15 hours after consumption of contaminated food. Nausea may accompany diarrhea, but vomiting (emesis) rarely occurs. Symptoms persist for 24 hours in most instances.

The emetic type of food poisoning is characterized by nausea and vomiting within 0.5 to 6 h after consumption of contaminated foods. Occasionally, abdominal cramps and/or diarrhea may also occur. Duration of symptoms is generally less than 24 h. The symptoms of this type of food poisoning parallel those caused by <u>Staphylococcus aureus</u> foodborne intoxication. Some strains of <u>B. subtilis</u> and <u>B. licheniformis</u> have been isolated from lamb and chicken incriminated in food poisoning episodes. These organisms demonstrate the production of a highly heat-stable toxin that may be similar to the vomiting type toxin produced by *B. cereus*.

The presence of large numbers of *B. cereus* (greater than 10^6 organisms/g) in a food is indicative of active growth and proliferation of the organism and is consistent with a potential hazard to health.

Confirmation of *B. cereus* as the etiologic agent in a foodborne outbreak requires either (1) isolation of strains of the same serotype from the suspect food and feces or vomitus of the patient, (2) isolation of large numbers of a *B. cereus* serotype known to cause foodborne illness from the suspect food or from the feces or vomitus of the patient, or (3) isolation of *B. cereus* from suspect foods and determining their enterotoxigenicity by serological (diarrheal toxin) or biological (diarrheal and emetic) tests. The rapid onset time to symptoms in the emetic form of disease, coupled with some food evidence, is often sufficient to diagnose this type of food poisoning.

A wide variety of foods including meats, milk, vegetables, and fish have been associated with the diarrheal type food poisoning. The vomiting6. Relative Frequency of Illness:

- 7. Complications:
- 8. Target Populations:
- 9. Food Analysis:

10. Selected Outbreaks:

type outbreaks have generally been associated with rice products; however, other starchy foods such as potato, pasta and cheese products have also been implicated. Food mixtures such as sauces, puddings, soups, casseroles, pastries, and salads have frequently been incriminated in food poisoning outbreaks.

In 1980, 9 outbreaks were reported to the Centers for Disease Control and included such foods as beef, turkey, and Mexican foods. In 1981, 8 outbreaks were reported which primarily involved rice and shellfish. Other outbreaks go unreported or are misdiagnosed because of symptomatic similarities to <u>Staphylococcus aureus</u> intoxication (*B. cereus* vomiting-type) or <u>C. perfringens</u> food poisoning (B. cereus diarrheal type).

Although no specific complications have been associated with the diarrheal and vomiting toxins produced by *B. cereus*, other clinical manifestations of *B. cereus* invasion or contamination have been observed. They include bovine mastitis, severe systemic and pyogenic infections, gangrene, septic meningitis, cellulitis, panophthalmitis, lung abscesses, infant death, and endocarditis.

All people are believed to be susceptible to *B. cereus* food poisoning. A variety of methods have been recommended for the recovery, enumeration and confirmation of *B. cereus* in foods. More recently, a serological method has been developed for detecting the putative enterotoxin of *B. cereus* (diarrheal type) isolates from suspect foods. Recent investigations suggest that the vomiting type toxin can be detected by animal models (cats, monkeys) or possibly by cell culture.

On September 22, 1985, the Maine Bureau of Health was notified of gastrointestinal illness among patrons of a Japanese restaurant. Because the customers were exhibiting symptoms of illness while still on the restaurant premises, and because uncertainty existed as to the etiology of the problem, the local health department, in concurrence with the restaurant owner, closed the restaurant at 7:30 p.m. that same day.

Eleven (31%) of the approximately 36 patrons reportedly served on the evening of September 22, were contacted in an effort to determine the etiology of the outbreak. Those 11 comprised the last three dining parties served on September 22. Despite extensive publicity, no additional cases were reported.

A case was defined as anyone who demonstrated vomiting or diarrhea within 6 hours of dining at the restaurant. All 11 individuals were interviewed for symptoms, time of onset of illness, illness duration, and foods ingested. All 11 reported nausea and vomiting; nine reported diarrhea; one reported headache; and one reported abdominal cramps. Onset of illness ranged from 30 minutes to 5 hours (mean 1 hour, 23 minutes) after eating at the restaurant. Duration of illness ranged from 5 hours to several days, except for two individuals still symptomatic with diarrhea 2 weeks after dining at the restaurant. Ten persons sought medical treatment at local emergency rooms on September 22; two ultimately required hospitalization for rehydration.

Analysis of the association of specific foods with illness was not instructive, since all persons consumed the same food items; chicken soup, fried shrimp, stir-fried rice, fried zucchini, onions, bean sprouts, cucumber, cabbage, and lettuce salad, ginger salad dressing, hibachi chicken and steak, and tea. Five persons ordered hibachi scallops, and one person ordered hibachi swordfish. However, most individuals

sampled each other's entrees. One vomitus specimen and two stool specimens from the three separate individuals yielded an overgrowth of *B. cereus*, although an accurate bacterial count could not be made because an inadequate amount of the steak remained for laboratory analysis. No growth of *B. cereus* was reported from the fried rice, mixed fried vegetables, or hibachi chicken.

According to the owner, all meat was delivered 2-3 times a week from a local meat supplier and refrigerated until ordered by restaurant patrons. Appropriate-sized portions for a dining group were taken from the kitchen to the dining area and diced or sliced, then sautéed at the table directly in front of restaurant patrons. The meat was seasoned with soy sauce salt and white pepper, open containers of which had been used for at least 2 months by the restaurant. The hibachi steak was served immediately after cooking.

The fried rice served with the meal was customarily made from leftover boiled rice. It could not be established whether the boiled rice had been stored refrigerated or at room temperature.

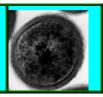

Fresh, rapidly cooked meat, eaten immediately, seems an unlikely vehicle of *B. cereus* food poisoning. The laboratory finding of *B. cereus* in a foodstuff without quantitative cultures and without accompanying epidemiologic data is insufficient to establish its role in the outbreak. Although no viable *B. cereus* organisms were isolated from the fried rice eaten with the meal, it does not exclude this food as the common vehicle. Reheating during preparation may have eliminated the bacteria in the food without decreasing the activity of the heat-stable toxin. While the question of the specific vehicle remains incompletely resolved, the clinical and laboratory findings substantially support *B. cereus* as the cause of the outbreak.

Most episodes of food poisoning undoubtedly go unreported, and in most of those reported, the specific pathogens are never identified. Alert recognition of the clinical syndrome and appropriate laboratory work permitted identification of the role of *B. cereus* in this outbreak.

For a report on a *B. cereus* outbreak in northern Virginia see this MMWR 43(10):1994 Mar 18.

For more information on recent outbreaks see the Morbidity and Mortality Weekly Reports from CDC.

Listeria monocytogenes

1. Name of the Organism: *Listeria monocytogenes*

2. Name of Acute Disease:

3. Nature of Disease:

4. Diagnosis of Human Illness:

5. Associated Foods:

This is a <u>Gram-positive bacterium</u>, motile by means of flagella. Some studies suggest that 1-10% of humans may be intestinal carriers of *L. monocytogenes*. It has been found in at least 37 mammalian species, both domestic and feral, as well as at least 17 species of birds and possibly some species of fish and shellfish. It can be isolated from soil, silage, and other environmental sources. *L. monocytogenes* is quite hardy and resists the deleterious effects of freezing, drying, and heat remarkably well for a bacterium that does not form spores. Most *L. monocytogenes* are pathogenic to some degree.

Listeriosis is the name of the general group of disorders caused by *L. monocytogenes*.

Listeriosis is clinically defined when the organism is isolated from blood, cerebrospinal fluid, or an otherwise normally sterile site (e.g. placenta, fetus).

The manifestations of listeriosis include septicemia, meningitis (or meningoencephalitis), encephalitis, and intrauterine or cervical infections in pregnant women, which may result in spontaneous abortion (2nd/3rd trimester) or stillbirth. The onset of the aforementioned disorders is usually preceded by influenza-like symptoms including persistent fever. It was reported that gastrointestinal symptoms such as nausea, vomiting, and diarrhea may precede more serious forms of listeriosis or may be the only symptoms expressed. Gastrointestinal symptoms were epidemiologically associated with use of antacids or cimetidine.. The onset time to serious forms of listeriosis is unknown but may range from a few days to three weeks. The onset time to gastrointestinal symptoms is unknown but is probably greater than 12 hours.

The infective dose of *L. monocytogenes* is unknown but is believed to vary with the strain and susceptibility of the victim. From cases contracted through raw or supposedly pasteurized milk, it is safe to assume that in susceptible persons, fewer than 1,000 total organisms may cause disease. *L. monocytogenes* may invade the gastrointestinal epithelium. Once the bacterium enters the host's monocytes, macrophages, or polymorphonuclear leukocytes, it is bloodborne (septicemic) and can grow. Its presence intracellularly in phagocytic cells also permits access to the brain and probably transplacental migration to the fetus in pregnant women. The pathogenesis of *L. monocytogenes* centers on its ability to survive and multiply in phagocytic host cells.

Listeriosis can only be positively diagnosed by culturing the organism from blood, cerebrospinal fluid, or stool (although the latter is difficult and of limited value).

L. monocytogenes has been associated with such foods as raw milk, supposedly pasteurized fluid milk, cheeses (particularly soft-ripened varieties), ice cream, raw vegetables, fermented raw-meat sausages, raw and cooked poultry, raw meats (all types), and raw and smoked fish. Its ability to grow at temperatures as low as 3oC permits multiplication in refrigerated foods.

6. Frequency of the Disease:

The 1987 incidence data prospectively collected by CDC suggests that there are at least 1600 cases of listeriosis with 415 deaths per year in the U.S. The vast majority of cases are sporadic, making epidemiological links to food very difficult.

Most healthy persons probably show no symptoms. The "complications" are the usual clinical expressions of the disease.

When listeric meningitis occurs, the overall mortality may be as high as 70%; from septicemia 50%, from perinatal/neonatal infections greater than 80%. In infections during pregnancy, the mother usually survives. Successful treatment with parenteral <u>penicillin</u> or <u>ampicillin</u> has been reported. <u>Trimethoprim-sulfamethoxazole</u> has been shown effective in patients allergic to penicillin.

The main target populations for listeriosis are:

pregnant women/fetus - perinatal and neonatal infections;

persons immunocompromised by corticosteroids, anticancer drugs, graft suppression therapy, <u>AIDS</u>;

cancer patients - leukemic patients particularly;

less frequently reported - diabetic, cirrhotic, asthmatic, and <u>ulcerative</u> <u>colitis</u> patients;

the elderly;

normal people--some reports suggest that normal, healthy people are at risk, although antacids or cimetidine may predispose. A listerosis outbreak in Switzerland involving cheese suggested that healthy uncompromised individuals could develop the disease, particularly if the foodstuff was heavily contaminated with the organism.

The methods for analysis of food are complex and time consuming. The present FDA method, revised in September, 1990, requires 24 and 48 hours of enrichment, followed by a variety of other tests. Total time to identification is from 5 to 7 days, but the announcement of specific nonradiolabled DNA probes should soon allow a simpler and faster confirmation of suspect isolates.

Recombinant DNA technology may even permit 2-3 day positive analysis in the future. Currently, FDA is collaborating in adapting its methodology to quantitate very low numbers of the organisms in foods.

8. Target Populations:

7. Complications:

9. Food Analysis:

	Outbreaks include the California episode in 1985, which was due to Mexican-style cheese and led to numerous stillbirths. As a result of this episode, FDA has been monitoring domestic and imported cheeses and has taken numerous actions to remove these products from the market when <i>L. monocytogenes</i> is found.
10. Selected Outbreaks:	There have been other clustered cases, such as in Philadelphia, PA, in 1987. Specific food linkages were only made epidemiologically in this cluster.
	CDC has established an epidemiological link between consumption of raw hot dogs or undercooked chicken and approximately 20% of the sporadic cases under prospective study.
	For more information on recent outbreaks see the Morbidity and Mortality Weekly Reports from CDC.
11. Education:	The <u>FDA health alert for Hispanic pregnant women</u> concerns the risk of listeriosis from soft cheeses. The CDC provides similar information <u>in Spanish.</u>
	The Food Safety and Inspection Service of the U.S. Department of Agriculture has jointly produced with the FDA a <u>background</u> document on <i>Listeria</i> and Listeriosis. FSIS also has updated consumer information on <u>Listeria</u> dated February 1999.
	The CDC produces an information brochure on preventing <u>Listeriosis</u> .
12. Other Resources:	A <u>Loci index for genome <i>Listeria monocytogenes</i> is available from GenBank.</u>

Clostridium perfringens

- **1. Name of Organism:** Clostridium perfringens
- Clostridium perfringens is an anaerobic, <u>Gram-positive</u>, sporeforming rod (anaerobic means unable to grow in the presence of free oxygen). It is widely distributed in the environment and frequently occurs in the intestines of humans and many domestic and feral animals. Spores of the organism persist in soil, sediments, and areas subject to human or animal fecal pollution.

2. Name of Acute Disease:

Perfringens food poisoning is the term used to describe the common foodborne illness caused by *C. perfringens*. A more serious but rare illness is also caused by ingesting food contaminated with Type C strains. The latter illness is known as enteritis necroticans or pig-bel disease.

3. Nature of Disease:

The common form of perfringens poisoning is characterized by intense abdominal cramps and diarrhea which begin 8-22 hours after consumption of foods containing large numbers of those *C. perfringens* bacteria capable of producing the food poisoning toxin. The illness is usually over within 24 hours but less severe symptoms may persist in some individuals for 1 or 2 weeks. A few deaths have been reported as a result of dehydration and other complications.

Necrotic enteritis (pig-bel) caused by *C. perfringens* is often fatal. This disease also begins as a result of ingesting large numbers of the causative bacteria in contaminated foods. Deaths from necrotic enteritis (pig-bel syndrome) are caused by infection and necrosis of the intestines and from resulting septicemia. This disease is very rare in the U.S.

Infective dose--The symptoms are caused by ingestion of large numbers (greater than 10 to the 8th) vegetative cells. Toxin production in the digestive tract (or in test tubes) is associated with sporulation. This disease is a food infection; only one episode has ever implied the possibility of intoxication (i.e., disease from preformed toxin).

4. Diagnosis of Human Illness:

Perfringens poisoning is diagnosed by its symptoms and the typical delayed onset of illness. Diagnosis is confirmed by detecting the toxin in the feces of patients. Bacteriological confirmation can also be done by finding exceptionally large numbers of the causative bacteria in implicated foods or in the feces of patients.

5. Associated Foods and Food Handling:

In most instances, the actual cause of poisoning by *C. perfringens* is temperature abuse of prepared foods. Small numbers of the organisms are often present after cooking and multiply to food poisoning levels during cool down and storage of prepared foods. Meats, meat products, and gravy are the foods most frequently implicated.

6. Frequency:

Perfringens poisoning is one of the most commonly reported foodborne illnesses in the U.S. There were 1,162 cases in 1981, in 28 separate outbreaks. At least 10-20 outbreaks have been reported annually in the U.S. for the past 2 decades. Typically, dozens or even hundreds of person are affected. It is probable that many outbreaks go unreported because the implicated foods or patient feces are not tested routinely for *C. perfringens* or its toxin. CDC estimates that about 10,000 actual cases occur annually in the U.S.

7. Usual Course of Disease and Complications:

The disease generally lasts 24 hours. In the elderly or infirm, symptoms may last 1-2 weeks. Complications and/or death only very rarely occur.

8. Target Populations:

Institutional feeding (such as school cafeterias, hospitals, nursing homes,

9. Analysis of Food and Feces:

10. Selected Outbreaks:

prisons, etc.) where large quantities of food are prepared several hours before serving is the most common circumstance in which perfringens poisoning occurs. The young and elderly are the most frequent victims of perfringens poisoning. Except in the case of pig-bel syndrome, complications are few in persons under 30 years of age. Elderly persons are more likely to experience prolonged or severe symptoms.

Standard bacteriological culturing procedures are used to detect the organism in implicated foods and in feces of patients. Serological assays are used for detecting enterotoxin in the feces of patients and for testing the ability of strains to produce toxin. The procedures take 1-3 days.

Since December 1981, FDA has investigated 10 outbreaks in 5 states. In two instances, more than one outbreak occurred in the same feeding facility within a 3-week period. One such outbreak occurred on 19 March 1984, involving 77 prison inmates. Roast beef served as a luncheon meat was implicated as the food vehicle and C. perfringens was confirmed as the cause by examining stools of 24 patients. Most of the patients became ill 8-16 hours after the meal. Eight days later, on 27 March 1984, a second outbreak occurred involving many of the same persons. The food vehicle was ham. Inadequate refrigeration and insufficient reheating of the implicated foods caused the outbreaks. Most of the other outbreaks occurred in institutional feeding environments: a hospital, nursing home, labor camp, school cafeteria, and at a fire house luncheon. In November, 1985, a large outbreak of C. perfringens gastroenteritis occurred among factory workers in Connecticut. Forty-four percent of the 1,362 employees were affected. Four main-course foods served at an employee banquet were associated with illness, but gravy was implicated by stratified analysis. The gravy had been prepared 12-24 hours before serving, had been improperly cooled, and was reheated shortly before serving. The longer the

A outbreak of *C. perfringens* in corned beef was reported in MMWR 43(8):1994 Mar 04.

reheating period, the less likely the gravy was to cause illness.

For more information on recent outbreaks see the <u>Morbidity and Mortality</u> Weekly Reports from CDC.

Clostridium botulinum

1. Name of the organism:

Clostridium botulinum

Clostridium botulinum is an anaerobic, <u>Gram-positive</u>, spore-forming rod that produces a potent <u>neurotoxin</u>. The <u>spores</u> are heat-resistant and can survive in foods that are incorrectly or minimally processed. Seven types (A, B, C, D, E, F and G) of <u>botulism</u> are recognized, based on the antigenic specificity of the toxin produced by each strain. Types A, B, E and F cause human botulism. Types C and D cause most cases of botulism in animals. Animals most commonly affected are wild fowl and poultry, cattle, horses and some species of fish. Although type G has been isolated from soil in Argentina, no outbreaks involving it have been recognized.

Foodborne botulism (as distinct from wound botulism and infant botulism) is a severe type of food poisoning caused by the ingestion of foods containing the potent neurotoxin formed during growth of the organism. The toxin is heat labile and can be destroyed if heated at 80oC for 10 minutes or longer. The incidence of the disease is low, but the disease is of considerable concern because of its high mortality rate if not treated immediately and properly. Most of the 10 to 30 outbreaks that are reported annually in the United States are associated with inadequately processed, home-canned foods, but occasionally commercially produced foods have been involved in outbreaks. Sausages, meat products, canned vegetables and seafood products have been the most frequent vehicles for human botulism.

The organism and its spores are widely distributed in nature. They occur in both cultivated and forest soils, bottom sediments of streams, lakes, and coastal waters, and in the intestinal tracts of fish and mammals, and in the gills and viscera of crabs and other shellfish.

2. Name of the Disease:

Four types of botulism are recognized: foodborne, infant, wound, and a form of botulism whose classification is as yet undetermined. Certain foods have been reported as sources of spores in cases of infant botulism and the undetermined category; wound botulism is not related to foods.

Foodborne botulism is the name of the disease (actually a foodborne intoxication) caused by the consumption of foods containing the neurotoxin produced by *C. botulinum*.

Infant botulism, first recognized in 1976, affects infants under 12 months of age. This type of botulism is caused by the ingestion of *C. botulinum* spores, which colonize and produce toxin in the intestinal tract of infants (intestinal toxemia botulism). Of the various potential environmental sources such as soil, cistern water, dust and foods, honey is the one dietary reservoir of *C. botulinum* spores thus far definitively linked to infant botulism by both laboratory and epidemiologic studies. The number of confirmed infant botulism cases has increased significantly as a result of greater awareness by health officials since its recognition in 1976. It is now internationally recognized, with cases being reported in more countries.

Wound botulism is the rarest form of botulism. The illness results when *C. botulinum* by itself or with other microorganisms infects a wound and produces toxins that reach other parts of the body via the blood stream. Foods are not involved in this type of botulism.

Undetermined category of botulism involves adult cases in which a specific food

or wound source cannot be identified. It has been suggested that some cases of botulism assigned to this category might result from intestinal colonization in adults, with in vivo production of toxin. Reports in the medical literature suggest the existence of a form of botulism similar to infant botulism, but occurring in adults. In these cases, the patients had surgical alterations of the gastrointestinal tract and/or antibiotic therapy. It is proposed that these procedures may have altered the normal gut flora and allowed *C. botulinum* to colonize the intestinal tract.

3. Nature of the Disease:

Infective dose -- a very small amount (a few nanograms) of toxin can cause illness.

Onset of symptoms in foodborne botulism is usually 18 to 36 hours after ingestion of the food containing the toxin, although cases have varied from 4 hours to 8 days. Early signs of intoxication consist of marked lassitude, weakness and vertigo, usually followed by double vision and progressive difficulty in speaking and swallowing. Difficulty in breathing, weakness of other muscles, abdominal distention, and constipation may also be common symptoms.

Clinical symptoms of infant botulism consist of constipation that occurs after a period of normal development. This is followed by poor feeding, lethargy, weakness, pooled oral secretions, and wail or altered cry. Loss of head control is striking. Recommended treatment is primarily supportive care. Antimicrobial therapy is not recommended. Infant botulism is diagnosed by demonstrating botulinal toxins and the organism in the infants' stools.

4. Diagnosis of Human Illness:

Although botulism can be diagnosed by clinical symptoms alone, differentiation from other diseases may be difficult. The most direct and effective way to confirm the clinical diagnosis of botulism in the laboratory is to demonstrate the presence of toxin in the serum or feces of the patient or in the food that the patient consumed. Currently, the most sensitive and widely used method for detecting toxin is the mouse neutralization test. This test takes 48 hours. Culturing of specimens takes 5-7 days.

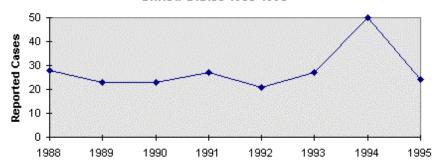

5. Associated Foods:

The types of foods involved in botulism vary according to food preservation and eating habits in different regions. Any food that is conducive to outgrowth and toxin production, that when processed allows spore survival, and is not subsequently heated before consumption can be associated with botulism. Almost any type of food that is not very acidic (pH above 4.6) can support growth and toxin production by *C. botulinum*. Botulinal toxin has been demonstrated in a considerable variety of foods, such as canned corn, peppers, green beans, soups, beets, asparagus, mushrooms, ripe olives, spinach, tuna fish, chicken and chicken livers and liver pate, and luncheon meats, ham, sausage, stuffed eggplant, lobster, and smoked and salted fish.

6. Frequency:

The incidence of the disease is low, but the mortality rate is high if not treated immediately and properly. There are generally 10 to 30 outbreaks a year in the United States. Some cases of botulism may go undiagnosed because symptoms are transient or mild, or misdiagnosed as Guillain-Barre syndrome.

Reported Cases Foodborne Botulism, United States 1988-1995

Summary of Notifiable Diseases, United States MMWR 44(53): 1996 October 25

- 7. The Usual Course of Disease and Complications:
- 8. Target Populations:
- 9. Food Analysis:
- 10. Selected Outbreaks:

Botulinum toxin causes flaccid paralysis by blocking motor nerve terminals at the myoneural junction. The flaccid paralysis progresses symmetrically downward, usually starting with the eyes and face, to the throat, chest and extremities. When the diaphragm and chest muscles become fully involved, respiration is inhibited and death from asphyxia results. Recommended treatment for foodborne botulism includes early administration of botulinal antitoxin (available from CDC) and intensive supportive care (including mechanical breathing assistance).

All people are believed to be susceptible to the foodborne intoxication. Since botulism is foodborne and results from ingestion of the toxin of *C. botulinum*, determination of the source of an outbreak is based on detection and identification of toxin in the food involved. The most widely accepted method is

identification of toxin in the food involved. The most widely accepted methor the injection of extracts of the food into passively immunized mice (mouse neutralization test). The test takes 48 hours. This analysis is followed by culturing all suspect food in an enrichment medium for the detection and isolation of the causative organism. This test takes 7 days.

Two separate outbreaks of botulism have occurred involving commercially canned salmon. Restaurant foods such as sautéed onions, chopped bottled garlic, potato salad made from baked potatoes and baked potatoes themselves have been responsible for a number of outbreaks. Also, smoked fish, both hot and cold-smoke (e.g., Kapchunka) have caused outbreaks of type E botulism.

In October and November, 1987, 8 cases of type E botulism occurred, 2 in New York City and 6 in Israel. All 8 patients had consumed Kapchunka, an uneviscerated, dry-salted, air-dried, whole whitefish. The product was made in New York City and some of it was transported by individuals to Israel. All 8 patients with botulism developed symptoms within 36 hours of consuming the Kapchunka. One female died, 2 required breathing assistance, 3 were treated therapeutically with antitoxin, and 3 recovered spontaneously. The Kapchunka involved in this outbreak contained high levels of type E botulinal toxin despite salt levels that exceeded those sufficient to inhibit *C. botulinum* type E outgrowth. One possible explanation was that the fish contained low salt levels when air-dried at room temperature, became toxic, and then were re-brined. Regulations were published to prohibit the processing, distribution and sale of Kapchunka and Kapchunka-type products in the United States.

A bottled chopped garlic-in-oil mix was responsible for three cases of botulism in Kingston, N.Y. Two men and a woman were hospitalized with botulism after consuming a chopped garlic-in-oil mix that had been used in a spread for garlic bread. The bottled chopped garlic relied solely on refrigeration to ensure safety and did not contain any additional antibotulinal additives or barriers. The FDA

	has ordered companies to stop making the product and to withdraw from the market any garlic-in-oil mix that does not include microbial inhibitors or acidifying agents and does not require refrigeration for safety.
	Since botulism is life-threatening, FDA always initiates a Class I recall.
	January 1992
	An incident of foodborne botulism in Oklahoma is reported in MMWR 44(11):1995 Mar 24.
	A botulism type B outbreak in Italy associated with eggplant in oil is reported in MMWR 44(2):1995 Jan 20.
	The botulism outbreak associated with salted fish mentioned above is reported in greater detail in MMWR 36(49):1987 Dec 18.
	For more information on recent outbreaks see the Morbidity and Mortality Weekly Reports from CDC.
11. Education:	The December 1995 issue of "FDA Consumer" has an article titled <u>Botulism</u> <u>Toxin: a Poison That Can Heal</u> which discusses Botulism toxin with an emphasis on its medical uses.

	A Loci index for genome Clostridium botulinum is available from GenBank.

Staphylococcus aureus

1. Name of the Organism:

Staphylococcus aureus

- 2. Name of Acute Disease:
- 3. Nature of the Disease:

4. Diagnosis of Human Illness:

5. Foods Incriminated:

S. aureus is a spherical bacterium (coccus) which on microscopic examination appears in pairs, short chains, or bunched, grape-like clusters. These organisms are <u>Gram-positive</u>. Some strains are capable of producing a highly heat-stable protein toxin that causes illness in humans.

<u>Staphylococcal food poisoning</u> (staphyloenterotoxicosis; staphyloenterotoxemia) is the name of the condition caused by the <u>enterotoxins</u> which some strains of *S. aureus* produce.

The onset of symptoms in staphylococcal food poisoning is usually rapid and in many cases acute, depending on individual susceptibility to the toxin, the amount of contaminated food eaten, the amount of toxin in the food ingested, and the general health of the victim. The most common symptoms are nausea, vomiting, retching, abdominal cramping, and prostration. Some individuals may not always demonstrate all the symptoms associated with the illness. In more severe cases, headache, muscle cramping, and transient changes in blood pressure and pulse rate may occur. Recovery generally takes two days, However, it us not unusual for complete recovery to take three days and sometimes longer in severe cases.

Infective dose--a toxin dose of less than 1.0 microgram in contaminated food will produce symptoms of staphylococcal intoxication. This toxin level is reached when *S. aureus* populations exceed 100000 per gram.

In the diagnosis of staphylococcal foodborne illness, proper interviews with the victims and gathering and analyzing epidemiologic data are essential. Incriminated foods should be collected and examined for staphylococci. The presence of relatively large numbers of enterotoxigenic staphylococci is good circumstantial evidence that the food contains toxin. The most conclusive test is the linking of an illness with a specific food or in cases where multiple vehicles exist, the detection of the toxin in the food sample(s). In cases where the food may have been treated to kill the staphylococci, as in pasteurization or heating, direct microscopic observation of the food may be an aid in the diagnosis. A number of serological methods for determining the enterotoxigenicity of *S. aureus* isolated from foods as well as methods for the separation and detection of toxins in foods have been developed and used successfully to aid in the diagnosis of the illness. Phage typing may also be useful when viable staphylococci can be isolated from the incriminated food, from victims, and from suspected carrier such as food handlers.

Foods that are frequently incriminated in staphylococcal food poisoning include meat and meat products; poultry and egg products; salads such as egg, tuna, chicken, potato, and macaroni; bakery products such as cream-filled pastries, cream pies, and chocolate eclairs; sandwich fillings; and milk and dairy products. Foods that require considerable handling during preparation and that are kept at slightly elevated temperatures after preparation are frequently involved in staphylococcal food poisoning.

Staphylococci exist in air, dust, sewage, water, milk, and food or on food equipment, environmental surfaces, humans, and animals. Humans and animals are the primary reservoirs. Staphylococci are present in the nasal passages and throats and on the hair and skin of 50 percent or more of healthy

individuals. This incidence is even higher for those who associate with or who come in contact with sick individuals and hospital environments. Although food handlers are usually the main source of food contamination in food poisoning outbreaks, equipment and environmental surfaces can also be sources of contamination with *S. aureus*. Human intoxication is caused by ingesting enterotoxins produced in food by some strains of *S. aureus*, usually because the food has not been kept hot enough (60°C, 140°F, or above) or cold enough (7.2°C, 45°F, or below).

6. Frequency of Illness:

The true incidence of staphylococcal food poisoning is unknown for a number of reasons, including poor responses from victims during interviews with health officials; misdiagnosis of the illness, which may be symptomatically similar to other types of food poisoning (such as vomiting caused by <u>Bacillus cereus</u> toxin); inadequate collection of samples for laboratory analyses; and improper laboratory examination. Of the bacterial pathogens causing foodborne illnesses in the U.S. (127 outbreaks, 7,082 cases recorded in 1983), 14 outbreaks involving 1,257 cases were caused by <u>S. aureus</u>. These outbreaks were followed by 11 outbreaks (1,153 cases) in 1984, 14 outbreaks (421 cases) in 1985, 7 outbreaks (250 cases) in 1986 and one reported outbreak (100 cases) in 1987.

7. Complications:

Death from staphylococcal food poisoning is very rare, although such cases have occurred among the elderly, infants, and severely debilitated persons.

8. Target Population:

All people are believed to be susceptible to this type of bacterial intoxication; however, intensity of symptoms may vary.

9. Analysis of Foods:

For detecting trace amounts of staphylococcal enterotoxin in foods incriminated in food poisoning, the toxin must be separated from food constituents and concentrated before identification by specific precipitation with antiserum (antienterotoxin) as follows. Two principles are used for the purpose: (1) the selective adsorption of the enterotoxin from an extract of the food onto ion exchange resins and (2) the use of physical and chemical procedures for the selective removal of food constituents from the extract, leaving the enterotoxin(s) in solution. The use of these techniques and concentration of the resulting products (as much as possible) has made it possible to detect small amounts of enterotoxin in food.

There are developed rapid methods based on monoclonal antibodies (e.g., <u>ELISA</u>, Reverse Passive Latex Agglutination), which are being evaluated for their efficacy in the detection of enterotoxins in food. These rapid methods can detect approximately 1.0 nanogram of toxin/g of food.

10. Typical Outbreak:

1,364 children became ill out of a total of 5,824 who had eaten lunch served at 16 elementary schools in Texas. The lunches were prepared in a central kitchen and transported to the schools by truck. Epidemiological studies revealed that 95% of the children who became ill had eaten a chicken salad. The afternoon of the day preceding the lunch, frozen chickens were boiled for 3 hours. After cooking, the chickens were deboned, cooled to room temperature with a fan, ground into small pieces, placed into I2-inch-deep aluminum pans and stored overnight in a walk-in refrigerator at 42-45 degrees .

The following morning, the remaining ingredients of the salad were added and the mixture was blended with an electric mixer. The food was placed in thermal containers and transported to the various schools at 9:30 AM to 10:30 AM, where it was kept at room temperature until served between 11:30 AM and noon. Bacteriological examination of the chicken salad revealed the presence of large numbers of *S. aureus*.

Contamination of the chicken probably occurred when it was deboned. The chicken was not cooled rapidly enough because it was stored in I2-inch-deep layers. Growth of the staphylococcus probably occurred also during the period

11. Atypical Outbreaks:

when the food was kept in the warm classrooms. Prevention of this incident would have entailed screening the individuals who deboned the chicken for carriers of the staphylococcus, more rapid cooling of the chicken, and adequate refrigeration of the salad from the time of preparation to its consumption.

In 1989, multiple staphylococcal foodborne diseases were associated with the consumption of canned mushrooms. (CDC Morbidity and Mortality Weekly Report, June 23, 1989, Vol. 38, #24.)

Starkville, Mississippi. On February 13, 22 people became ill with gastroenteritis several hours after eating at a university cafeteria. Symptoms included nausea, vomiting, diarrhea, and abdominal cramps. Nine people were hospitalized. Canned mushrooms served with omelets and hamburgers were associated with illness. No deficiencies in food handling were found. Staphylococcal enterotoxin type A was identified in a sample of implicated mushrooms from the omelet bar and in unopened cans from the same lot.

Queens, New York, On February 28, 48 people became ill a median of 3 hours after eating lunch in a hospital employee cafeteria. One person was hospitalized. Canned mushrooms served at the salad bar were epidemiologically implicated. Two unopened cans of mushrooms from the same lot as the implicated can contained staphylococcal enterotoxin A.

McKeesport, Pennsylvania. On April 17, 12 people became ill with gastroenteritis a median of 2 hours after eating lunch or dinner at a restaurant. Two people were hospitalized. Canned mushrooms, consumed on pizza or with a parmigiana sauce, were associated with illness. No deficiencies were found in food preparation or storage. Staphylococcal enterotoxin was found in samples of remaining mushrooms and in unopened cans from the same lot.

Philipsburg, Pennsylvania. On April 22, 20 people developed illness several hours after eating food from a take-out pizzeria. Four people were hospitalized. Only pizza served with canned mushrooms was associated with illness. Staphylococcal enterotoxin was found in a sample of mushrooms from the pizzeria and in unopened cans with the same lot number.

For more information on recent outbreaks see the <u>Morbidity and Mortality</u> <u>Weekly Reports</u> from CDC.

12. Other Resources:

A Loci index for genome Staphylococcus aureus is available from GenBank.

Streptococcus spp.

1. Name of the Organism:

Streptococcus spp.

2. Name of Acute Disease:

3. Nature of Illness/Disease:

4. Diagnosis of Human Disease:

5. Associated Foods:

6. Relative Frequency of Infection:

7. Usual Course of Disease and Complications:

8. Target Population:

9. Analysis of Foods:

The genus Streptococcus is comprised of <u>Gram-positive</u>, microaerophilic cocci (round), which are not motile and occur in chains or pairs. The genus is defined by a combination of antigenic, hemolytic, and physiological characteristics into Groups A, B, C, D, F, and G. Groups A and D can be transmitted to humans via food.

Group A: one species with 40 antigenic types (S. pyogenes).

Group D: five species (S. faecalis, S. faecium, S. durans, S. avium, and S. bovis).

Group A: Cause septic sore throat and <u>scarlet fever</u> as well as other pyogenic and septicemic infections.

Group D: May produce a clinical syndrome similar to staphylococcal intoxication.

Group A: Sore and red throat, pain on swallowing, tonsilitis, high fever, headache, nausea, vomiting, malaise, rhinorrhea; occasionally a rash occurs, onset 1-3 days; the infectious dose is probably quite low (less than 1,000 organisms).

Group D: Diarrhea, abdominal cramps, nausea, vomiting, fever, chills, dizziness in 2-36 hours. Following ingestion of suspect food, the infectious dose is probably high (greater than 107 organisms).

Group A: Culturing of nasal and throat swabs, pus, sputum, blood, suspect food, environmental samples.

Group D: Culturing of stool samples, blood, and suspect food.

Group A: Food sources include milk, ice cream, eggs, steamed lobster, ground ham, potato salad, egg salad, custard, rice pudding, and shrimp salad. In almost all cases, the foodstuffs were allowed to stand at room temperature for several hours between preparation and consumption. Entrance into the food is the result of poor hygiene, ill food handlers, or the use of unpasteurized milk.

Group D: Food sources include sausage, evaporated milk, cheese, meat croquettes, meat pie, pudding, raw milk, and pasteurized milk. Entrance into the food chain is due to underprocessing and/or poor and unsanitary food preparation.

Group A infections are low and may occur in any season, whereas Group D infections are variable.

Group A: Streptococcal sore throat is very common, especially in children. Usually it is successfully treated with antibiotics. Complications are rare; the fatality rate is low. Group D: Diarrheal illness is poorly characterized, but is acute and self-limiting.

All individuals are susceptible. No age or race susceptibilities have been found.

Suspect food is examined microbiologically by selective enumeration techniques, which can take up to 7 days. Group specificities are determined by Lancefield group-specific antisera.

10. Selected Outbreaks:

Group A: Outbreaks of septic sore throat and scarlet fever were numerous before the advent of milk pasteurization. Salad bars have been suggested as possible sources of infection. Most current outbreaks have involved complex foods (i.e., salads) which were infected by a food handler with septic sore throat. One ill food handler may subsequently infect hundreds of individuals.

Group D: Outbreaks are not common and are usually the result of preparing, storing, or handling food in an unsanitary manner.

For more information on recent outbreaks see the <u>Morbidity and Mortality Weekly Reports</u> from CDC.

Aeromonas hydrophila

1. Name of the Organism:

Aeromonas hydrophila, Aeromonas caviae, Aeromonas sobria & (Aeromonas veronii?)

2. Name of Acute Disease:

3. Nature of Disease:

4. Diagnosis of Human Illness:

5. Associated Foods:

6. Relative Frequency of Disease:

<u>Aeromonas hydrophila</u> is a species of bacterium that is present in all freshwater environments and in brackish water. Some strains of A. hydrophila are capable of causing illness in fish and amphibians as well as in humans who may acquire infections through open wounds or by ingestion of a sufficient number of the organisms in food or water.

Not as much is known about the other Aeromonas spp., but they too are aquatic microorganisms and have been implicated in human disease.

A. hydrophila may cause gastroenteritis in healthy individuals or septicemia in individuals with impaired immune systems or various malignancies.

A. caviae and A. sobria also may cause enteritis in anyone or septicemia in immunocompromised persons or those with malignancies.

At the present time, there is controversy as to whether A. hydrophila is a cause of human gastroenteritis. Although the organism possesses several attributes which could make it pathogenic for humans, volunteer human feeding studies, even with enormous numbers of cells (i.e. 10^11), have failed to elicit human illness. Its presence in the stools of individuals with diarrhea, in the absence of other known enteric pathogens, suggests that it has some role in disease.

Likewise, A. caviae and A. sobria are considered by many as "putative pathogens," associated with diarrheal disease, but as of yet they are unproven causative agents.

Two distinct types of gastroenteritis have been associated with A. hydrophila: a cholera-like illness with a watery (rice and water) diarrhea and a dysenteric illness characterized by loose stools containing blood and mucus. The infectious dose of this organism is unknown, but SCUBA divers who have ingested small amounts of water have become ill, and A. hydrophila has isolated from their stools.

A general infection in which the organisms spread throughout the body has been observed in individuals with underlying illness (septicemia).

A. hydrophila can be cultured from stools or from blood by plating the organisms on an agar medium containing sheep blood and the antibiotic ampicillin. Ampicillin prevents the growth of most competing microorganisms. The species identification is confirmed by a series of biochemical tests. The ability of the organism to produce the enterotoxins believed to cause the gastrointestinal symptoms can be confirmed by tissue culture assays.

A. hydrophila has frequently been found in fish and shellfish. It has also been found in market samples of red meats (beef, pork, lamb) and poultry. Since little is known about the virulence mechanisms of A. hydrophila, it is presumed that not all strains are pathogenic, given the ubiquity of the organism.

The relative frequency of A. hydrophila disease in the U.S. is unknown since efforts to ascertain its true incidence have only recently been attempted. Most cases have been sporadic rather than associated with large outbreaks, but increased reports have been noted from several clinical centers.

On rare occasions the dysentery-like syndrome is severe and may last for several weeks. A. hydrophila may spread throughout the body and cause a general 7. Usual Course of Disease infection in persons with impaired immune systems. Those at risk are and Some Complications: individuals suffering from leukemia, carcinoma, and cirrhosis and those treated with immunosuppressive drugs or who are undergoing cancer chemotherapy. All people are believed to be susceptible to gastroenteritis, although it is most frequently observed in very young children. People with impaired 8. Target Populations: immune systems or underlying malignancy are susceptible to the more severe infections. A. hydrophila can be recovered from most foods by direct plating onto a 9. Analysis of Foods: solid medium containing starch as the sole carbohydrate source and ampicillin to retard the growth of most competing microorganisms. Most cases have been sporadic, rather than associated with large 10. Selected Outbreaks: outbreaks. For more information on recent outbreaks see the Morbidity and Mortality Weekly Reports from CDC.

Miscellaneous enterics

1. Name of the Organism:

Miscellaneous enterics, Gram-negative genera including: *Klebsiella*, *Enterobacter*, *Proteus*, *Citrobacter*, *Aerobacter*, *Providencia*, *Serratia*

2. Name of Acute Disease:

3. Nature of Disease:

4. Diagnosis of Human Illness

5. Associated Foods:

6. Relative Frequency of Disease:

7. Usual Course of Disease and Some Complications:

These rod-shaped enteric (intestinal) bacteria have been suspected of causing acute and chronic gastrointestinal disease. The organisms may be recovered from natural environments such as forests and freshwater as well as from farm produce (vegetables) where they reside as normal microflora. They may be recovered from the stools of healthy individuals with no disease symptoms. The relative proportion of pathogenic to nonpathogenic strains is unknown.

Gastroenteritis is name of the disease occasionally and sporadically caused by these genera.

Acute gastroenteritis is characterized by two or more of the symptoms of vomiting, nausea, fever, chills, abdominal pain, and watery (dehydrating) diarrhea occurring 12-24 hours after ingestion of contaminated food or water. Chronic diarrheal disease is characterized by dysenteric symptoms: foul-smelling, mucus-containing, diarrheic stool with flatulence and abdominal distention. The chronic disease may continue for months and require antibiotic treatment.

Infectious dose--unknown. Both the acute and chronic forms of the disease are suspected to result from the elaboration of enterotoxins. These organisms may become transiently virulent by gaining mobilizeable genetic elements from other pathogens. For example, pathogenic <u>Citrobacter freundii</u>, which elaborated a toxin identical to E. coli heat-stable toxin, was isolated from the stools of ill children.

Recovery and identification methods for these organisms from food, water or diarrheal specimens are based upon the efficacy of selective media and results of microbiological and biochemical assays. The ability to produce enterotoxin(s) may be determined by cell culture assay and animal bioassays, serological methods, or genetic probes.

These bacteria have been recovered from dairy products, raw shellfish, and fresh raw vegetables. The organisms occur in soils used for crop production and shellfish harvesting waters and, therefore, may pose a health hazard.

Acute gastrointestinal illness may occur more frequently in undeveloped areas of the world. The chronic illness is common in malnourished children living in unsanitary conditions in tropical countries.

Healthy individuals recover quickly and without treatment from the acute form of gastrointestinal disease. Malnourished children (1-4 years) and infants who endure chronic diarrhea soon develop structural and functional abnormalities of their intestinal tracts resulting in loss of ability to absorb nutrients. Death is not uncommon in these children and results indirectly from the chronic toxigenic effects that produce the malabsorption and malnutrition.

All people may be susceptible to pathogenic forms of these bacteria. Protracted illness is more commonly experienced by the very young.

These strains are recovered by standard selective and differential isolation procedures for enteric bacteria. Biochemical and in vitro assays may be used to determine species and pathogenic potential. Not being usually thought of as human pathogens, they may easily be overlooked by the clinical microbiology laboratory. Intestinal infections with these species in the U.S. have usually taken the form of sporadic cases of somewhat doubtful etiology.

Citrobacter freundii was suspected by CDC of causing an outbreak of diarrheal disease in Washington, DC. Imported

Camembert cheese was incriminated.

For more information on recent outbreaks see the Morbidity and Mortality Weekly Reports from CDC.

Objectives

On completion of this section, participants will be able to:

- Discuss the major differences between bacteria and viral foodborne agents.
- Identify the important routes and agents of foodborne transmission.
- Identify the important foodborne viruses.
- Discuss the control of viral foodborne illness.

Introduction

Unlike bacteria, viruses are not alive. Viruses are much smaller than bacteria and consist of a protein coat, which encloses a nucleic acid core. They are what are called "obligate intracellular parasites". The virus attaches to a susceptible cell and injects its nucleic acid into the cell. It takes over the host cell producing millions of new viruses and destroys the cell in the process. Viruses only infect a particular type of cell in a particular species of animal. So the ones we have to worry about only infect human beings. Only a small number are needed to make someone ill.

When viruses are in a food, they are simply there and do not replicate or increase in number. Viruses are extremely persistent and may remain in a contaminated food for long periods of time. To increase the number of virus particles to make them easier to detect, you have to grow them in a susceptible host cell. Currently, there are no susceptible host cells other than humans for the viruses associated with foodborne illness so detection is difficult.

Foods are contaminated with viruses in four major ways:

- Contaminated Estuarine¹ Water
- Contaminated Irrigation Water
- Contaminated drinking water
- Poor Personal Hygiene

Sewage-polluted estuarine waters can contaminate fish and shellfish. Oysters, clams and mussels, which are filter feeders, entrap the pathogens from the water in their mucous membranes and transfer them to their digestive tract. If the shellfish is consumed whole and raw, so are the viruses. The surfaces of other estuarine species can also get contaminated but most of these are not consumed raw. In order to be a problem, they must be recontaminated after cooking by use of equipment or utensils that had been contaminated through contact with raw seafood or infected employees.

<u>Contaminated irrigation water</u> can deposit viruses on the surface of fruits and vegetables. Again, it is generally foods that are consumed raw that are of concern.

Viruses can be introduced if <u>contaminated drinking water</u> is used to wash or transport food, or is used as an ingredient in the food, or if you just drink it.

Viruses can be added to food by infected food handlers with fecal material on their hands, a result of <u>poor personal hygiene practices</u>. Sometimes such people are noticeably ill, but other times they are without symptoms, and are just carriers of the virus. Ready-to-eat products such as bakery and deli items are of particular concern but virtually any food may cause illness if it is contaminated with human fecal matter containing the virus.

The viruses covered in this document include:

- Hepatitis A virus
- Hepatitis E virus
- Rotavirus
- Norwalk virus group
- Other viral agents

¹ Estuarine water refers to an area of water – an estuary – where the tide meets a river – or an arm of the sea at the lower end of a river. Estuarine water then relates to water that is formed in the estuary.

Hepatitis A Virus

- 1. Name of the Organism: Hepatitis A Virus
- 2. Name of Acute Disease:
- 3. Nature of Disease:
- 4. Diagnosis of Human Illness:
- 5. Associated Foods:

6. Frequency of Disease:

Hepatitis A virus (HAV) is classified with the enterovirus group of the Picornaviridae family. HAV has a single molecule of RNA surrounded by a small (27 nm diameter) protein capsid and a buoyant density in CsCl of 1.33 g/ml. Many other picornaviruses cause human disease, including polioviruses, coxsackieviruses, echoviruses, and rhinoviruses (cold viruses).

The term hepatitis A (HA) or type A viral hepatitis has replaced all previous designations: infectious hepatitis, epidemic hepatitis, epidemic jaundice, catarrhal jaundice, infectious icterus, Botkins disease, and MS-1 hepatitis.

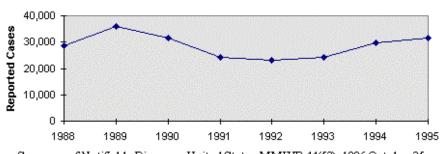

Hepatitis A is usually a mild illness characterized by sudden onset of fever, malaise, nausea, anorexia, and abdominal discomfort, followed in several days by jaundice. The infectious dose is unknown but presumably is 10-100 virus particles.

Hepatitis A is diagnosed by finding IgM-class anti-HAV in serum collected during the acute or early convalescent phase of disease. Commercial kits are available.

HAV is excreted in feces of infected people and can produce clinical disease when susceptible individuals consume contaminated water or foods. Cold cuts and sandwiches, fruits and fruit juices, milk and milk products, vegetables, salads, shellfish, and iced drinks are commonly implicated in outbreaks. Water, shellfish, and salads are the most frequent sources. Contamination of foods by infected workers in food processing plants and restaurants is common.

Hepatitis A has a worldwide distribution occurring in both epidemic and sporadic fashions. About 22,700 cases of hepatitis A representing 38% of all hepatitis cases (5-year average from all routes of transmission) are reported annually in the U.S. In 1988 an estimated 7.3% cases were foodborne or waterborne. HAV is primarily transmitted by person-to-person contact through fecal contamination, but common-source epidemics from contaminated food and water also occur. Poor sanitation and crowding facilitate transmission. Outbreaks of HA are common in institutions, crowded house projects, and prisons and in military forces in adverse situations. In developing countries, the incidence of disease in adults is relatively low because of exposure to the virus in childhood. Most individuals 18 and older demonstrate an immunity that provides lifelong protection against reinfection. In the U.S., the percentage of adults with immunity increases with age (10% for those 18-19 years of age to 65% for those over 50). The increased number of susceptible individuals allows common source epidemics to evolve rapidly.

Reported cases of Hepatitis A, United States 1988-1995

Summary of Notifiable Diseases, United States MMWR 44(53): 1996 October 25

7. Usual Course of Disease:

The incubation period for hepatitis A, which varies from 10 to 50 days (mean 30 days), is dependent upon the number of infectious particles consumed. Infection with very few particles results in longer incubation periods. The period of communicability extends from early in the incubation period to about a week after the development of jaundice. The greatest danger of spreading the disease to others occurs during the middle of the incubation period, well before the first presentation of symptoms. Many infections with HAV do not result in clinical disease, especially in children. When disease does occur, it is usually mild and recovery is complete in 1-2 weeks. Occasionally, the symptoms are severe and convalescence can take several months. Patients suffer from feeling chronically tired during convalescence, and their inability to work can cause financial loss. Less than 0.4% of the reported cases in the U.S. are fatal. These rare deaths usually occur in the elderly.

8. Target Population:

All people who ingest the virus and are immunologically unprotected are susceptible to infection. Disease however, is more common in adults than in children.

9. Analysis of Foods:

The virus has not been isolated from any food associated with an outbreak. Because of the long incubation period, the suspected food is often no longer available for analysis. No satisfactory method is presently available for routine analysis of food, but sensitive molecular methods used to detect HAV in water and clinical specimens, should prove useful to detect virus in foods. Among those, the PCR amplification method seems particularly promising.

Hepatitis A is endemic throughout much of the world. Major national epidemics occurred in 1954, 1961 and 1971. Although no major epidemic occurred in the 1980s, the incidence of hepatitis A in the U.S. increased 58% from 1983 to 1989. Foods have been implicated in over 30 outbreaks since 1983. The most recent ones and the suspected contaminated foods include:

1987 - Louisville, Kentucky. Suspected source: imported lettuce.

10. Selected Outbreaks:

1988 - Alaska. Ice-slush beverage prepared in a local market. - North Carolina. Iced tea prepared in a restaurant. - Florida. Raw oysters harvested from nonapproved bed.

1989 - Washington. Unidentified food in a restaurant chain.

1990 - North Georgia. Frozen strawberries. - Montana. Frozen strawberries. - Baltimore. Shellfish.

A summary of foodborne Hepatitis A outbreaks in Missouri, Wisconsin, and Alaska is found in MMWR 42(27):1993 Jul 16.

MMWR 39(14):1990 Apr 13 summarizes foodborne outbreaks of Hepatitis A in Alaska, Florida, North Carolina, Washington.

For more information on recent outbreaks see the <u>Morbidity and Mortality</u> <u>Weekly Reports</u> from CDC.

Back to Virus List

Hepatitis E Virus

1. Name of the Organism: Hepatitis E Virus Hepatitis E Virus (HEV) has a particle diameter of 32-34 nm, a buoyant density of 1.29 g/ml in KTar/Gly gradient, and is very labile. Serologically related smaller (27-30 nm) particles are often found in feces of patients with Hepatitis E and are presumed to represent degraded viral particles. HEV has a single-stranded polyadenylated RNA genome of approximately 8 kb. Based on its physicochemical properties it is presumed to be a calici-like virus.

2. Name of Acute Disease:

The disease caused by HEV is called hepatitis E, or enterically transmitted non-A non-B hepatitis (ET-NANBH). Other names include fecal-oral non-A non-B hepatitis, and A-like non-A non-B hepatitis.

3. Nature of Disease:

Note: This disease should not be confused with hepatitis C, also called parenterally transmitted non-A non-B hepatitis (PT-NANBH), or B-like non-A non-B hepatitis, which is a common cause of hepatitis in the U.S.

4. Diagnosis of Human Illness:

Hepatitis caused by HEV is clinically indistinguishable from hepatitis A disease. Symptoms include malaise, anorexia, abdominal pain, arthralgia, and fever. The infective dose is not known.

5. Associated Foods:

and by exclusion of hepatitis A and B viruses by serological tests. Confirmation requires identification of the 27-34 nm virus-like particles by immune electron microscopy in feces of acutely ill patients.

Diagnosis of HEV is based on the epidemiological characteristics of the outbreak

6. Frequency of Disease:

HEV is transmitted by the fecal-oral route. Waterborne and person-to-person spread have been documented. The potential exists for foodborne transmission.

7. Usual Course of Disease and Some Complications:

Hepatitis E occurs in both epidemic and sporadic-endemic forms, usually associated with contaminated drinking water. Major waterborne epidemics have occurred in Asia and North and East Africa. To date no U.S. outbreaks have been reported.

The incubation period for hepatitis E varies from 2 to 9 weeks. The disease usually

is mild and resolves in 2 weeks, leaving no sequelae. The fatality rate is 0.1-1%

8. Target Populations:

except in pregnant women. This group is reported to have a fatality rate approaching 20%.

The disease is most often seen in young to middle aged adults (15-40 years old). Pregnant women appear to be exceptionally susceptible to severe disease, and

excessive mortality has been reported in this group.

9. Analysis of Foods:

HEV has not been isolated from foods. No method is currently available for routine analysis of foods.

10. History of Recent Outbreaks:

Major waterborne epidemics have occurred in India (1955 and 1975-1976), USSR (1955-1956), Nepal (1973), Burma (1976-1977), Algeria (1980-1981), Ivory Coast (1983-1984), in refugee camps in Eastern Sudan and Somalia (1985-6), and most recently in Borneo (1987). The first outbreaks reported in the American continents occurred in Mexico in late 1986. To date, no outbreak has occurred in the U.S., but imported cases were identified in Los Angeles in 1987. There is no evidence for immunity against this agent in the American population. Thus, unless other factors (such as poor sanitation or prevalence of other enteric pathogens) are important, the potential for spread to the U.S. is great. Good sanitation and personal hygiene are the best preventive measures.

For more information on recent outbreaks see the <u>Morbidity and Mortality</u> <u>Weekly Reports</u> from CDC.

Back to Virus List

Rotavirus

- **1. Name of the Organism:** Rotavirus
- 2. Name of Acute Disease:
- 3. Nature of Disease:

4. Diagnosis of Human Illness:

5. Associated Foods:

6. Frequency of Disease:

Rotaviruses are classified with the <u>Reoviridae</u> family. They have a genome consisting of 11 double-stranded RNA segments surrounded by a distinctive two-layered protein capsid. Particles are 70 nm in diameter and have a buoyant density of 1.36 g/ml in CsCl. Six serological groups have been identified, three of which (groups A, B, and C) infect humans.

Rotaviruses cause acute gastroenteritis. Infantile diarrhea, winter diarrhea, acute nonbacterial infectious gastroenteritis, and acute viral gastroenteritis are names applied to the infection caused by the most common and widespread group A rotavirus.

Rotavirus gastroenteritis is a self-limiting, mild to severe disease characterized by vomiting, watery diarrhea, and low-grade fever. The infective dose is presumed to be 10-100 infectious viral particles. Because a person with rotavirus diarrhea often excretes large numbers of virus (108-1010 infectious particles/ml of feces), infection doses can be readily acquired through contaminated hands, objects, or utensils. Asymptomatic rotavirus excretion has been well documented and may play a role in perpetuating endemic disease.

Specific diagnosis of the disease is made by identification of the virus in the patient's stool. Enzyme immunoassay (EIA) is the test most widely used to screen clinical specimens, and several commercial kits are available for group A rotavirus. Electron microscopy (EM) and polyacrylamide gel electrophoresis (PAGE) are used in some laboratories in addition or as an alternative to EIA. A reverse transcription-polymerase chain reaction (RT-PCR) has been developed to detect and identify all three groups of human rotaviruses.

Rotaviruses are transmitted by the fecal-oral route. Person-to-person spread through contaminated hands is probably the most important means by which rotaviruses are transmitted in close communities such as pediatric and geriatric wards, day care centers and family homes. Infected food handlers may contaminate foods that require handling and no further cooking, such as salads, fruits, and hors d'oeuvres. Rotaviruses are quite stable in the environment and have been found in estuary samples at levels as high as 1-5 infectious particles/gal. Sanitary measures adequate for bacteria and parasites seem to be ineffective in endemic control of rotavirus, as similar incidence of rotavirus infection is observed in countries with both high and low health standards.

Group A rotavirus is endemic worldwide. It is the leading cause of severe diarrhea among infants and children, and accounts for about half of the cases requiring hospitalization. Over 3 million cases of rotavirus gastroenteritis occur annually in the U.S. In temperate areas, it occurs primarily in the winter, but in the tropics it occurs throughout the year. The number attributable to food contamination is unknown.

Group B rotavirus, also called adult diarrhea rotavirus or ADRV, has caused major epidemics of severe diarrhea affecting thousands of persons of all ages in China.

Group C rotavirus has been associated with rare and sporadic cases of diarrhea in children in many countries. However, the first outbreaks were reported from Japan and England.

The incubation period ranges from 1-3 days. Symptoms often start with vomiting followed by 4-8 days of diarrhea. Temporary lactose intolerance may occur. Recovery is usually complete. However, severe diarrhea without fluid and electrolyte replacement may result in severe diarrhea 7. Usual Course of Disease: and death. Childhood mortality caused by rotavirus is relatively low in the U.S., with an estimated 100 cases/year, but reaches almost 1 million cases/year worldwide. Association with other enteric pathogens may play a role in the severity of the disease. Humans of all ages are susceptible to rotavirus infection. Children 6 months to 2 years of age, premature infants, the elderly, and the 8. Target Populations: immunocompromised are particularly prone to more severe symptoms caused by infection with group A rotavirus. The virus has not been isolated from any food associated with an outbreak, and no satisfactory method is available for routine analysis of food. However, it should be possible to apply procedures that have been 9. Analysis of Foods: used to detect the virus in water and in clinical specimens, such as enzyme immunoassays, gene probing, and PCR amplification to food analysis. Outbreaks of group A rotavirus diarrhea are common among hospitalized infants, young children attending day care centers, and elder persons in nursing homes. Among adults, multiple foods served in banquets were implicated in 2 outbreaks. An outbreak due to contaminated municipal water occurred in Colorado, 1981. Several large outbreaks of group B rotavirus involving millions of persons as a result of sewage contamination of drinking water supplies have occurred in China since 1982. Although to date outbreaks caused by group B rotavirus have been confined to mainland China, 10. Selected Outbreaks: seroepidemiological surveys have indicated lack of immunity to this group of virus in the U.S. The newly recognized group C rotavirus has been implicated in rare and isolated cases of gastroenteritis. However, it was associated with three outbreaks among school children: one in Japan, 1989, and two in England, 1990. For a discussion of rotavirus surveillance in the US, see MMWR 40(5)1991 Feb 8.

11. Other Resources:

The Norwalk virus family

1. Name of the Organism: The Norwalk virus family

- 2. Name of Acute Disease:
- 3. Nature of Disease:
- 4. Diagnosis of Human Illness:

5. Associated Foods:

6. Frequency of Disease:

7. Usual Course of Disease and

Norwalk virus is the prototype of a family of unclassified small round structured viruses (SRSVs) which may be related to the <u>caliciviruses</u>. They contain a positive strand RNA genome of 7.5 kb and a single structural protein of about 60 kDa. The 27-32 nm viral particles have a buoyant density of 1.39-1.40 g/ml in CsCl. The family consists of several serologically distinct groups of viruses that have been named after the places where the outbreaks occurred. In the U.S., the Norwalk and Montgomery County agents are serologically related but distinct from the Hawaii and Snow Mountain agents. The Taunton, Moorcroft, Barnett, and Amulree agents were identified in the U.K., and the Sapporo and Otofuke agents in Japan. Their serological relationships remain to be determined.

Common names of the illness caused by the Norwalk and Norwalk-like viruses are viral gastroenteritis, acute nonbacterial gastroenteritis, food poisoning, and food infection.

The disease is self-limiting, mild, and characterized by nausea, vomiting, diarrhea, and abdominal pain. Headache and low-grade fever may occur. The infectious dose is unknown but presumed to be low.

Specific diagnosis of the disease can only be made by a few laboratories possessing reagents from human volunteer studies. Identification of the virus can be made on early stool specimens using immune electron microscopy and various immunoassays. Confirmation often requires demonstration of seroconversion, the presence of specific IgM antibody, or a four-fold rise in antibody titer to Norwalk virus on paired acute-convalescent sera.

Norwalk gastroenteritis is transmitted by the fecal-oral route via contaminated water and foods. Secondary person-to-person transmission has been documented. Water is the most common source of outbreaks and may include water from municipal supplies, well, recreational lakes, swimming pools, and water stored aboard cruise ships.

Shellfish and salad ingredients are the foods most often implicated in Norwalk outbreaks. Ingestion of raw or insufficiently steamed clams and oysters poses a high risk for infection with Norwalk virus. Foods other than shellfish are contaminated by ill food handlers.

Only the common cold is reported more frequently than viral gastroenteritis as a cause of illness in the U.S. Although viral gastroenteritis is caused by a number of viruses, it is estimated that Norwalk viruses are responsible for about 1/3 of the cases not involving the 6-to-24-month age group. In developing countries the percentage of individuals who have developed immunity is very high at an early age. In the U.S. the percentage increases gradually with age, reaching 50% in the population over 18 years of age. Immunity, however, is not permanent and reinfection can occur.

A mild and brief illness usually develops 24-48 h after

Some Complications:

8. Target Populations:

9. Analysis of Foods:

10. Selected Outbreaks:

contaminated food or water is consumed and lasts for 24-60 hours. Severe illness or hospitalization is very rare.

All individuals who ingest the virus and who have not (within 24 months) had an infection with the same or related strain, are susceptible to infection and can develop the symptoms of gastroenteritis. Disease is more frequent in adults and older children than in the very young.

The virus has been identified in clams and oysters by radioimmunoassay. The genome of Norwalk virus has been cloned and development of gene probes and PCR amplification techniques to detect the virus in clinical specimens and possibly in food are under way.

Foodborne outbreaks of gastroenteritis caused by Norwalk virus are often related to consumption of raw shellfish. Frequent and widespread outbreaks, reaching epidemic proportions, occurred in Australia (1978) and in the state of New York (1982) among consumers of raw clams and oysters. From 1983 to 1987, ten well documented outbreaks caused by Norwalk virus were reported in the U.S., involving a variety of foods: fruits, salads, eggs, clams, and bakery items.

Preliminary evidence suggests that Norwalk virus caused large outbreaks of gastroenteritis that occurred in Pennsylvania and Delaware in September, 1987. The source of both outbreaks was traced to ice made with water from a contaminated well. In Pennsylvania, the ice was consumed at a football game, and in Delaware, at a cocktail party. Norwalk virus is also suspected to have caused an outbreak aboard a cruise ship in Hawaii in 1990. Fresh fruits were the probable vehicle of contamination.

Snow Mountain virus was implicated in an outbreak in a retirement community in California (1988) which resulted in two deaths. Illness was associated with consumption of shrimp probably contaminated by food handlers.

For outbreaks of Norwalk virus see \underline{MMWR} 42(49):1993 Dec 17 and this \underline{MMWR} 43(24):1994 Jun 24 as well.

The multistate outbreak of viral gastroenteritis associated with consumption of oysters from Apalachicola Bay, Florida, December 1994-January 1995 is reported in MMWR 44(2):1995 Jan 20.

For more information on recent outbreaks see the Morbidity and Mortality Weekly Reports from CDC.

Back to Virus List

Other Gastroenteritis Viruses

1. Name of the Organism:
Other viruses associated with gastroenteritis

- 2. Name of Acute Disease:
- 3. Nature of Disease:
- 4. Diagnosis of Human Illness:

Although the rotavirus and the Norwalk family of viruses are the leading causes of viral gastroenteritis, a number of other viruses have been implicated in outbreaks, including <u>astroviruses</u>, <u>caliciviruses</u>, enteric <u>adenoviruses</u> and <u>parvovirus</u>. Astroviruses, caliciviruses, and the Norwalk family of viruses possess well-defined surface structures and are sometimes identified as "small round structured viruses" or SRSVs. Viruses with smooth edge and no discernible surface structure are designated "featureless viruses" or "small round viruses" (SRVs). These agents resemble enterovirus or parvovirus, and may be related to them.

Astroviruses are unclassified viruses that contain a single positive strand of RNA of about 7.5 kb surrounded by a protein capsid of 28-30 nm diameter. A five or six pointed star shape can be observed on the particles under the electron microscope. Mature virions contain two major coat proteins of about 33 kDa each and have a buoyant density in CsCl of 1.38 - 1.40 g/ml. At least five human serotypes have been identified in England. The Marin County agent found in the U.S. is serologically related to astrovirus type 5.

Caliciviruses are classified in the family Caliciviridae. They contain a single strand of RNA surrounded by a protein capsid of 31-40 nm diameter. Mature virions have cup-shaped indentations which give them a 'Star of David' appearance in the electron microscope. The particle contain a single major coat protein of 60 kDa and have a buoyant density in CsCl of 1.36 - 1.39 g/ml. Four serotypes have been identified in England.

Enteric adenoviruses represent serotypes 40 and 41 of the family Adenoviridae. These viruses contain a double-stranded DNA surrounded by a distinctive protein capsid of about 70 nm diameter. Mature virions have a buoyant density in CsCl of about 1.345 g/ml.

Parvoviruses belong to the family Parvoviridae, the only group of animal viruses to contain linear single-stranded DNA. The DNA genome is surrounded by a protein capsid of about 22 nm diameter. The buoyant density of the particle in CsCl is 1.39-1.42 g/ml. The Ditchling, Wollan, Paramatta, and cockle agents are candidate parvoviruses associated with human gastroenteritis.

Common names of the illness caused by these viruses are acute nonbacterial infectious gastroenteritis and viral gastroenteritis.

Viral gastroenteritis is usually a mild illness characterized by nausea, vomiting, diarrhea, malaise, abdominal pain, headache, and fever. The infectious dose is not known but is presumed to be low.

Some laboratories possessing appropriate reagents can make specific diagnosis of the disease. Identification of the virus present in early acute stool samples is made by immune electron microscopy and various enzyme immunoassays. Confirmation often requires demonstration of seroconversion to the agent by serological tests on acute and convalescent serum pairs.

5. Associated Foods:

6. Frequency of Disease:

7. Usual Course of Disease and Some Complications:

8. Target Population:

Viral gastroenteritis is transmitted by the fecal-oral route via person-to-person contact or ingestion of contaminated foods and water. Ill food handlers may contaminate foods that are not further cooked before consumption. The respiratory route may also transmit enteric adenovirus. Shellfish have been implicated in illness caused by a parvo-like virus.

Astroviruses cause sporadic gastroenteritis in children under 4 years of age and account for about 4% of the cases hospitalized for diarrhea. Most American and British children over 10 years of age have antibodies to the virus.

Caliciviruses infect children between 6 and 24 months of age and account for about 3% of hospital admissions for diarrhea. By 6 years of age, more than 90% of all children have developed immunity to the illness.

The enteric adenovirus causes 5-20% of the gastroenteritis in young children, and is the second most common cause of gastroenteritis in this age group. By 4 years of age, 85% of all children have developed immunity to the disease. Parvo-like viruses have been implicated in a number of shellfish-associated outbreaks, but the frequency of disease is unknown.

A mild, self limiting illness usually develops 10 to 70 hours after contaminated food or water is consumed and lasts for 2 to 9 days. The clinical features are milder but otherwise indistinguishable from rotavirus gastroenteritis. Co-infections with other enteric agents may result in more severe illness lasting a longer period of time.

The target populations for astro and caliciviruses are young children and the elderly. Only young children seem to develop illness caused by the enteric adenoviruses. Infection with these viruses is widespread and seems to result in development of immunity. Parvoviruses infect all age groups and probably do not elicit a permanent immunity.

9. Analysis of Foods:

10. Selected Outbreaks:

Only a parvovirus-like agent (cockle) has been isolated from seafood associated with an outbreak. Although foods are not routinely analyzed for these viruses, it may be possible to apply current immunological procedures to detect viruses in clinical specimens. Gene probes and PCR detection methods are currently being developed.

Outbreaks of astrovirus and calicivirus occur mainly in child care settings and nursing homes. In the past decade, 7 outbreaks of calicivirus and 4 of astrovirus have been reported from England and Japan. In California, an outbreak caused by an astrovirus, the Marin County agent, occurred among elderly patients in a convalescent hospital. No typical calicivirus has been implicated in outbreaks in the U.S. However, if Norwalk and Norwalk-like viruses prove to be caliciviruses, they would account for most food and waterborne outbreaks of gastroenteritis in this country.

Outbreaks of adenovirus have been reported in England and Japan, all involving children in hospitals or day care centers.

The small featureless, parvo-like viruses caused outbreaks of gastroenteritis in primary and secondary schools in England (Ditchling and Wollan) and Australia (Paramatta). The cockle agent caused a large community-wide outbreak in England (1977) associated with consumption of contaminated seafood. Parvo-like viruses were also implicated in several outbreaks that occurred in the States of New York and Louisiana in 1982-1983.

For more information on recent outbreaks see the <u>Morbidity</u> and <u>Mortality Weekly Reports</u> from CDC.

Back to Virus List

Viruses and Shellfish

Pathogenic viruses that enter shellfish waters tend to accumulate in sediments, where they can persist for months. They survive better at lower, winter temperatures, which is when most of the shellfish are harvested for human consumption. Pathogenic viruses have been isolated from both "opened" and "closed" waters, and from shellfish harvested from each. Once taken in by shellfish, the viruses may persist for months. Illegal harvesting of shellfish from unapproved waters may exacerbate the problem of shellfish-borne viral illness.

In clean seawater, contaminated molluscan shellfish naturally eliminate pathogens from their digestive tracts through normal feeding, digestion, and excretion. In a process called relaying, shellfish from contaminated waters are transferred to clean waters where they filter feed for a predetermined period of time to eliminate bacteria and viruses from their systems. In depuration, shellfish are placed in tanks with purified flowing water or recirculating seawater and are allowed to filter-feed. Depuration conditions are closely controlled so the process usually takes two to three days, while relaying can take two or more weeks. Generally, the removal of viruses takes longer than removal of bacteria. So, elimination of bacteria is not a reliable indicator of viral elimination.

Control of Viruses

Both Hepatitis A virus and the Norwalk agent are resistant to extremes of pH and are extremely stable at both refrigeration and freezing temperatures. There appears to be resistance to heat and radiation treatments as well. Most control measures have been evaluated in shellfish only. One interesting note is that shellfish tissue is quite protective and therefore pathogenic viruses are fairly heat resistant there.

Transmission of human viral disease by consumption of cooked shellfish has been documented epidemiologically. Hepatitis A virus is still infective when treated at 133° F for 30 minutes in shellfish. Cooking conditions such as frying, steaming, baking, and stewing result in only a ten-fold reduction of viruses. Heat treatments necessary to completely inactivate viruses in shellfish generally result in a product that is organoleptically unacceptable. Other products that are heated to temperatures of 180°F should be free of the virus.

On the other hand, chlorine is an effective agent to inactivate these viruses in waters, provided the water is relatively clear prior to chlorination.

Control of viruses:

- Clean shellfish water
- Clean irrigation water
- Clean drinking water
- Proper hygienic practices by food handlers

The most effective control for viruses is preventing contamination of food products in the first place. Shellfish must be harvested from waters that are not contaminated by sewage. Crops must not be irrigated with fecal contaminated water. Drinking water must be from a safe source, or properly treated. And employees must conform to hygienic practices.

Vaccination for HAV is available to the general public. It has been suggested that HAV vaccination be required of all food handlers. Passive immunization with gamma globulin following exposure to HAV or in anticipation of possible exposure continues to be done. However this must occur in a timely manner. It does not provide immunity. It is expensive, and there are difficulties in identifying all exposed individuals. Norwalk and SRSV's immunity is temporary and vaccination efficacy will most likely be limited.

Parasites

Objectives

- Discuss the parasites and corresponding life cycle stage in regards to food products.
- Discuss the potential for the presence and transmission of food borne parasites.
- Discuss the measures that may be taken to decrease the incidence, prevent contamination, or eliminate transmission of parasites through food products.

General Concepts

- No reproduction or multiplication while in or on food products, reproduction requires a specific host or of group of host.
- Corollary to the above statement transmission of parasites to a new host (the consumer) only occurs when a particular life cycle stage is present.
- Second corollary enrichment techniques used in microbiology are often ineffective in analysis for parasites. Many parasites have a low infectious dose
- The longer incubation period for parasitic infections (often 7 10 days)
 makes traceback efforts for epidemiological studies difficult.
- Many control measures are available, but particular life cycle stages of some parasites may be very resistant to selected measures.

This section will discuss some of the more important parasitic associated foodborne illness. The discussion will cover some of the most important illnesses caused by protozoa and parasitic worms including:

- Giardia lamblia
- Entamoeba histolytica
- Cryptosporidium parvum
- Cyclospora cayetanensis
- Anisakis sp. and related worms
- Diphyllobothrium spp.
- Nanophyetus spp.
- Eustrongylides sp.
- Acanthamoeba and other free-living amoebae
- Ascaris lumbricoides and Trichuris trichiura

Giardia lamblia

- **1. Name of the organism:** *Giardia lamblia*
- 2. Disease Name:

3. Nature of the disease:

- 4. Diagnosis of Human Illness:
- 5. Associated Foods:

Giardia lamblia (intestinalis) is a single celled animal, i.e., a protozoa, that moves with the aid of five flagella. In Europe, it is sometimes referred to as Lamblia intestinalis.

Giardiasis is the most frequent cause of non-bacterial diarrhea in North America.

Organisms that appear identical to those that cause human illness have been isolated from domestic animals (dogs and cats) and wild animals (beavers and bears). A related but morphologically distinct organism infects rodents, although rodents may be infected with human isolates in the laboratory. Human giardiasis may involve diarrhea within 1 week of ingestion of the cyst, which is the environmental survival form and infective stage of the organism. Normally illness lasts for 1 to 2 weeks, but there are cases of chronic infections lasting months to years. Chronic cases, both those with defined immune deficiencies and those without, are difficult to treat. The disease mechanism is unknown, with some investigators reporting that the organism produces a toxin while others are unable to confirm its existence. The organism has been demonstrated inside host cells in the duodenum, but most investigators think this is such an infrequent occurrence that it is not responsible for disease symptoms. Mechanical obstruction of the absorptive surface of the intestine has been proposed as a possible pathogenic mechanism, as has a synergistic relationship with some of the intestinal flora. Giardia can be excysted, cultured and encysted in vitro; new isolates have bacterial, fungal, and viral symbionts. Classically the disease was diagnosed by demonstration of the organism in stained fecal smears. Several strains of *G. lamblia* have been isolated and described through analysis of their proteins and DNA; type of strain, however, is not consistently associated with disease severity. Different individuals show various degrees of symptoms when infected with the same strain, and the symptoms of an individual may vary during the course of the disease.

Infectious Dose - Ingestion of one or more cysts may cause disease, as contrasted to most bacterial illnesses where hundreds to thousands of organisms must be consumed to produce illness.

Giardia lamblia is frequently diagnosed by visualizing the organism, either the trophozoite (active reproducing form) or the cyst (the resting stage that is resistant to adverse environmental conditions) in stained preparations or unstained wet mounts with the aid of a microscope. A commercial fluorescent antibody kit is available to stain the organism. Sedimentation or flotation may concentrate organisms; however, these procedures reduce the number of recognizable organisms in the sample. An enzyme linked immunosorbant assay (ELISA) that detects excretory secretory products of the organism is also available. So far, the increased sensitivity of indirect serological detection has not been consistently demonstrated.

Giardiasis is most frequently associated with the consumption of contaminated water. Five outbreaks have been traced to food contamination by infected or infested food handlers, and the possibility of infections from contaminated vegetables that are eaten raw cannot

6. Relative Frequency of Disease:	be excluded. Cool moist conditions favor the survival of the organism. Giardiasis is more prevalent in children than in adults, possibly because many individuals seem to have a lasting immunity after infection. This organism is implicated in 25% of the cases of gastrointestinal disease and may be present asymptomatically. The overall incidence of infection in the United States is estimated at 2% of the population. This disease afflicts many homosexual men, both HIV-positive and HIV-negative individuals. This is presumed to be due to sexual transmission. The disease is also common in child day care centers, especially those in which diapering is done.
7. Complications:	About 40% of those who are diagnosed with giardiasis demonstrate disaccharide intolerance during detectable infection and up to 6 months after the infection can no longer be detected. Lactose (i.e., milk sugar) intolerance is most frequently observed. Some individuals (less than 4%) remain symptomatic more than 2 weeks; chronic infections lead to a malabsorption syndrome and severe weight loss. Chronic cases of giardiasis in immunodeficient and normal individuals are frequently refractile to drug treatment. Flagyl is normally quite effective in terminating infections. In some immune deficient individuals, giardiasis may contribute to a shortening of the life span.
8. Target Populations:	Giardiasis occurs throughout the population, although the prevalence is higher in children than adults. Chronic symptomatic giardiasis is more common in adults than children.
9. Food Analysis:	Food is analyzed by thorough surface cleaning of the suspected food and sedimentation of the organisms from the cleaning water. Feeding to specific pathogen-free animals has been used to detect the organism in large outbreaks associated with municipal water systems. The precise sensitivity of these methods has not been determined, so that negative results are questionable. Seven days may be required to detect an experimental infection.
10. Selected outbreaks:	Major outbreaks are associated with contaminated water systems that do not use sand filtration or have a defect in the filtration system. The largest reported foodborne outbreak involved 24 of 36 persons who consumed macaroni salad at a picnic.
	For more information on recent outbreaks see the Morbidity and Mortality Weekly Reports from CDC.
11. FDA Regulations or Activity:	FDA is actively developing and improving methods of recovering parasitic protozoa and helminth eggs from foods. Current recovery methods are published in the FDA's <u>Bacteriological Analytical Manual</u> .

Entamoeba histolytica

infects predo mammals su usually do no organism) with transmission. host and in from and soils and latter. When so the trophozoi described in the trophozoi

4. Diagnosis of Human Illness:

5. Transmission:

6. Frequency of Infections:

7. Usual Course of the Disease and Some Complications:

This is a single celled parasitic animal, i.e., a protozoa, that infects predominantly humans and other primates. Diverse mammals such as dogs and cats can become infected but usually do not shed cysts (the environmental survival form of the organism) with their feces, thus do not contribute significantly to transmission. The active (trophozoite) stage exists only in the host and in fresh feces; cysts survive outside the host in water and soils and on foods, especially under moist conditions on the latter. When swallowed they cause infections by excysting (to the trophozoite stage) in the digestive tract.

<u>Amebiasis</u> (or amoebiasis) is the name of the infection caused by *E. histolytica*.

Infections that sometimes last for years may be accompanied by 1) no symptoms, 2) vague gastrointestinal distress, 3) dysentery (with blood and mucus). Most infections occur in the digestive tract but other tissues may be invaded. Complications include 4) ulcerative and abscess pain and, rarely, 5) intestinal blockage. Onset time is highly variable. It is theorized that the absence of symptoms or their intensity varies with such factors as 1) strain of amoeba, 2) immune health of the host, and 3) associated bacteria and, perhaps, viruses. The amoeba's enzymes help it to penetrate and digest human tissues; it secretes toxic substances.

Infectious Dose--Theoretically, the ingestion of one viable cyst can cause an infection.

Human cases are diagnosed by finding cysts shed with the stool; various flotation or sedimentation procedures have been developed to recover the cysts from fecal matter; stains (including fluorescent antibody) help to visualize the isolated cysts for microscopic examination. Since cysts are not shed constantly, a minimum of 3 stools should be examined. In heavy infections, the motile form (the trophozoite) can be seen in fresh feces. Serological tests exist for long-term infections. It is important to distinguish the *E. histolytica* cyst from the cysts of nonpathogenic intestinal protozoa by its appearance.

Amebiasis is transmitted by fecal contamination of drinking water and foods, but also by direct contact with dirty hands or objects as well as by sexual contact.

The infection is "not uncommon" in the tropics and arctics, but also in crowded situations of poor hygiene in temperate-zone urban environments. It is also frequently diagnosed among homosexual men.

In the majority of cases, amoebas remain in the gastrointestinal tract of the hosts. Severe ulceration of the gastrointestinal mucosal surfaces occurs in less than 16% of cases. In fewer cases, the parasite invades the soft tissues, most commonly the liver. Only rarely are masses formed (amoebomas) that lead to intestinal obstruction. Fatalities are infrequent.

8. Target Populations:

All people are believed to be susceptible to infection, but individuals with a damaged or undeveloped immunity may suffer more severe forms of the disease. <u>AIDS/ARC</u> patients are very vulnerable.

9. Analysis of Foods:

E. histolytica cysts may be recovered from contaminated food by methods similar to those used for recovering <u>Giardia lamblia</u> cysts from feces. Filtration is probably the most practical method for recovery from drinking water and liquid foods. E. histolytica cysts must be distinguished from cysts of other parasitic (but nonpathogenic) protozoa and from cysts of free-living protozoa. Recovery procedures are not very accurate; cysts are easily lost or damaged beyond recognition, which leads to many falsely negative results in recovery tests. (See the FDA <u>Bacteriological Analytical Manual.</u>)

10. Selected Outbreaks:

The most dramatic incident in the USA was the Chicago World's Fair outbreak in 1933 caused by contaminated drinking water; defective plumbing permitted sewage to contaminate the drinking water. There were 1,000 cases (with 58 deaths). In recent times, food handlers are suspected of causing many scattered infections, but there has been no single large outbreak.

For more information on recent outbreaks see the Morbidity and Mortality Weekly Reports from CDC.

Cryptosporidium parvum

1. Name of the organism: *Cryptosporidium parvum*

- 2. Disease Name:
- 3. Nature of Acute Disease:

- 4. Diagnosis of Human Illness:
- 5. Food Occurrence:
- 6. Relative Frequency of the Disease:
- 7. Usual Course of the Disease and Complications:

Cryptosporidium parvum, a single-celled animal, i.e., a protozoa, is an obligate intracellular parasite. It has been given additional species names when isolated from different hosts. It is currently thought that the form infecting humans is the same species that causes disease in young calves. The forms that infect avian hosts and those that infect mice are not thought capable of infecting humans. Cryptosporidium sp. infects many herd animals (cows, goats, sheep among domesticated animals, and deer and elk among wild animals). The infective stage of the organism, the oocyst is 3 um in diameter or about half the size of a red blood cell. The sporocysts are resistant to most chemical disinfectants, but are susceptible to drying and the ultraviolet portion of sunlight. Some strains appear to be adapted to certain hosts but crossstrain infectivity occurs and may or may not be associated with illness. The species or strain infecting the respiratory system is not currently distinguished from the form infecting the intestines.

Intestinal, tracheal, or pulmonary cryptosporidiosis.

Intestinal cryptosporidiosis is characterized by severe watery diarrhea but may, alternatively, be asymptomatic. Pulmonary and tracheal cryptosporidiosis in humans is associated with coughing and frequently a low-grade fever; these symptoms are often accompanied by severe intestinal distress.

Infectious dose--Less than 10 organisms and, presumably, one organism can initiate an infection. The mechanism of disease is not known; however, the intracellular stages of the parasite can cause severe tissue alteration.

Oocysts are shed in the infected individual's feces. Sugar flotation is used to concentrate the organisms and acid fast staining is used to identify them. A commercial kit is available that uses fluorescent antibody to stain the organisms isolated from feces. Diagnosis has also been made by staining the trophozoites in intestinal and biopsy specimens. Pulmonary and tracheal cryptosporidiosis are diagnosed by biopsy and staining.

Cryptosporidium sp. could occur, theoretically, on any food touched by a contaminated food handler. Incidence is higher in child day care centers that serve food. Fertilizing salad vegetables with manure is another possible source of human infection. Large outbreaks are associated with contaminated water supplies.

Direct human surveys indicate a prevalence of about 2% of the population in North America. Serological surveys indicate that 80% of the population has had cryptosporidiosis. The extent of illness associated with reactive sera is not known.

Intestinal cryptosporidiosis is self-limiting in most healthy individuals, with watery diarrhea lasting 2-4 days. In some outbreaks at day care centers, diarrhea has lasted 1 to 4 weeks. To date, there is no known effective drug for the treatment of cryptosporidiosis. Immunodeficient individuals, especially AIDS

patients, may have the disease for life, with the severe watery diarrhea contributing to death. Invasion of the pulmonary system may also be fatal. In animals, the young show the most severe symptoms. For the most part, pulmonary infections are confined to those who are immunodeficient. However, an infant with a presumably normal 8. Target Populations: immune system had tracheal cryptosporidiosis (although a concurrent viremia may have accounted for lowered resistance). Child day care centers, with a large susceptible population, frequently report outbreaks. The 7th edition of FDA's Bacteriological Analytical Manual will 9. Analysis of Foods: contain a method for the examination of vegetables for Cryptosporidium sp. Since 1984, cryptosporidiosis has been associated with outbreaks of diarrheal illness in child day care centers throughout the United States and Canada. During 1987 a waterborne outbreak in Georgia produced illness in an estimated 13,000 individuals, and exposure to contaminated drinking water was the major distinction between those that were ill and those that were not. This was the first report of disease transmission by a municipal water system that was in compliance with all state and federal standards for An outbreak of cryptosporidiosis associated with the consumption of apple cider is reported in MMWR 46(1):1997 Jan 10. 10. Selected Outbreaks: MMWR 45(36):1996 Sep 13 reports on an outbreak of cryptosporidiosis associated with the consumption of home-made chicken salad in Minnesota. A non-food outbreak of cryptosporidiosis in a day-camp is reported in MMWR 45(21):1996 May 31. This report is linked to this chapter to provide reference information. MMWR 39(20):1990 May 25 reports on a non-food related outbreak of cryptosporidiosis, but contains useful information on Cryptosporidium sp. For more information on recent outbreaks see the Morbidity and Mortality Weekly Reports from CDC. FDA is developing and improving methods for the recovery of cysts of parasitic protozoa from fresh vegetables. Current 11. FDA Regulations or Activity: recovery methods are published in the Bacteriological Analytical Manual. 12. Education: The CDC has information on Cryptosporidium. From GenBank there is a Loci index for genome Cryptosporidium 13. Other Resources: parvum.

Anisakis simplex and related worms

1. Name of the Organism:

Anisakis simplex and related worms

2. Name of Acute Disease:

3. Nature of the Acute Disease:

4. Diagnosis of Human Illness:

Anisakis simplex (herring worm), Pseudoterranova (Phocanema, Terranova) decipiens (cod or seal worm), Contracaecum spp., and Hysterothylacium (Thynnascaris) spp. are anisakid nematodes (roundworms) that have been implicated in human infections caused by the consumption of raw or undercooked seafood. To date, only A. simplex and P. decipiens are reported from human cases in North America.

Anisakiasis is generally used when referring to the acute disease in humans. Some purists utilize generic names (e.g., contracaeciasis) in referring to the disease, but the majority consider that the name derived from the family is specific enough. The range of clinical features is not dependent on species of anisakid parasite in cases reported to date.

In North America, anisakiasis is most frequently diagnosed when the affected individual feels a tingling or tickling sensation in the throat and coughs up or manually extracts a nematode. In more severe cases there is acute abdominal pain, much like acute appendicitis accompanied by a nauseous feeling. Symptoms occur from as little as an hour to about 2 weeks after consumption of raw or undercooked seafood. One nematode is the usual number recovered from a patient. With their anterior ends, these larval nematodes from fish or shellfish usually burrow into the wall of the digestive tract to the level of the muscularis mucosae (occasionally they penetrate the intestinal wall completely and are found in the body cavity). They produce a substance that attracts eosinophils and other host white blood cells to the area. The infiltrating host cells form a granuloma in the tissues surrounding the penetrated worm. In the digestive tract lumen, the worm can detach and reattach to other sites on the wall. Anisakids rarely reach full maturity in humans and usually are eliminated spontaneously from the digestive tract lumen within 3 weeks of infection. Penetrated worms that die in the tissues are eventually removed by the host's phagocytic cells.

In cases where the patient vomits or coughs up the worm, the disease may be diagnosed by morphological examination of the nematode. (*Ascaris lumbricoides*, the large roundworm of humans, is a terrestrial relative of anisakines and sometimes these larvae also crawl up into the throat and nasal passages.) Other cases may require a fiber optic device that allows the attending physician to examine the inside of the stomach and the first part of the small intestine. These devices are equipped with a mechanical forceps that can be used to remove the worm. Other cases are diagnosed upon finding a granulomatous lesion with a worm on laparotomy. A specific radioallergosorbent test has been developed for anasakiasis, but is not yet commercially marketed.

5. Associated Foods:

6. Relative Frequency of the Disease:

7. Usual Disease Course and Complications:

8. Target Populations:

9. Analysis of Foods:

10. Selected Outbreaks:

Seafoods are the principal sources of human infections with these larval worms. The adults of A. simplex are found in the stomachs of whales and dolphins. Fertilized eggs from the female parasite pass out of the host with the host's feces. In seawater, the eggs embryonate, developing into larvae that hatch in sea water. These larvae are infective to copepods (minute crustaceans related to shrimp) and other small invertebrates. The larvae grow in the invertebrate and become infective for the next host, a fish or larger invertebrate host such as a squid. The larvae may penetrate through the digestive tract into the muscle of the second host. Some evidence exists that the nematode larvae move from the viscera to the flesh if the fish hosts are not gutted promptly after catching. The life cycles of all the other anisakid genera implicated in human infections are similar. These parasites are known to occur frequently in the flesh of cod, haddock, fluke, pacific salmon, herring, flounder, and monkfish.

Fewer than 10 cases are diagnosed in the U.S. annually. However, it is suspected that many other cases go undetected. The disease is transmitted by raw, undercooked or insufficiently frozen fish and shellfish, and its incidence is expected to increase with the increasing popularity of sushi and sashimi bars.

Severe cases of anisakiasis are extremely painful and require surgical intervention. Physical removal of the nematode(s) from the lesion is the only known method of reducing the pain and eliminating the cause (other than waiting for the worms to die). The symptoms apparently persist after the worm dies since some lesions are found upon surgical removal that contain only nematode remnants. Stenosis (a narrowing and stiffening) of the pyloric sphincter was reported in a case in which exploratory laparotomy had revealed a worm that was not removed.

The target population consists of consumers of raw or underprocessed seafood.

Candling or examining fish on a light table is used by commercial processors to reduce the number of nematodes in certain white-flesh fish that are known to be infected frequently. This method is not totally effective, nor is it very adequate to remove even the majority of nematodes from fish with pigmented flesh.

This disease is known primarily from individual cases. Japan has the greatest number of reported cases because of the large volume of raw fish consumed there.

A recent letter to the editor of the New England Journal of Medicine (319:1128-29, 1988) stated that approximately 50 cases of anisakiasis have been documented in the United States, to date. Three cases in the San Francisco Bay area involved ingestion of sushi or undercooked fish. The letter also points out that anasakiasis is easily misdiagnosed as acute appendicitis, Crohn's disease, gastric ulcer, or gastrointestinal cancer.

11. FDA Activity and Regulations:

For more information on recent outbreaks see the Morbidity and Mortality Weekly Reports from CDC.

FDA recommends that all fish and shellfish intended for raw (or semiraw such as marinated or partly cooked) consumption be blast frozen to –35 degrees C (-31 degrees F) or below for 15 hours, or be regularly frozen to –20 degrees C (-4 degrees F) or below for 7 days.

Diphyllobothrium spp.

- 1. Name of the Organism: *Diphyllobothrium* spp.
- 2. Name of the Acute Disease:

3. Nature of the Acute Disease:

- 4. Diagnosis of Human Illness:
- 5. Associated Foods:
- 6. Relative Frequency of Disease:
- 7. Usual Course of the Disease and Complications:
- 8. Target Populations:
- 9. Analysis of Foods:
- 10. Selected Outbreaks:

Diphyllobothrium latum and other members of the genus are broad fish tapeworms reported from humans. They are parasitic flatworms.

Diphyllobothriasis is the name of the disease caused by broad fish tapeworm infections.

Diphyllobothriasis is characterized by abdominal distention. flatulence, intermittent abdominal cramping, and diarrhea with onset about 10 days after consumption of raw or insufficiently cooked fish. The larva that infects people, a "plerocercoid," is frequently encountered in the viscera of freshwater and marine fishes. D. latum is sometimes encountered in the flesh of freshwater fish or fish that are anadromous (migrating from salt water to fresh water for breeding). Bears and humans are the final or definitive hosts for this parasite. D. latum is a broad, long tapeworm, often growing to lengths between 1 and 2 meters (3-7 feet) and potentially capable of attaining 10 meters (32 feet); the closely related D. pacificum normally matures in seals or other marine mammals and reaches only about half the length of D. latum. Treatment consists of administration of the drug. niclosamide, which is available to physicians through the Centers for Disease Control's Parasitic Disease Drug Service.

The disease is diagnosed by finding operculate eggs (eggs with a lid) in the patient's feces on microscopical examination. These eggs may be concentrated by sedimentation but not by flotation. They are difficult to distinguish from the eggs of <u>Nanophyetus</u> <u>spp.</u>.

The larvae of these parasites are sometimes found in the flesh of fish.

Diphyllobothriasis is rare in the United States, although it was formerly common around the Great Lakes and known as "Jewish or Scandinavian housewife's disease" because the preparers of gefilte fish or fish balls tended to taste these dishes before they were fully cooked. The parasite is now supposedly absent from Great Lakes fish. Recently, cases have been reported from the West Coast.

In persons that are genetically susceptible, usually persons of Scandinavian heritage, a severe anemia may develop as the result of infection with broad fish tapeworms. The anemia results from the tapeworm's great requirement for and absorption of Vitamin B12.

Consumers of raw and underprocessed fish are the target population for diphyllobothriasis.

Foods are not routinely analyzed for larvae of *D. latum*, but microscopic inspection of thin slices of fish, or digestion, can be used to detect this parasite in fish flesh.

An outbreak involving four Los Angeles physicians occurred in 1980. These physicians all consumed sushi (a raw fish dish) made of tuna, red snapper, and salmon. Others who did not

consume the sushi made with salmon did not contract diphyllobothriasis. At the time of this outbreak there was also a general increase in requests for niclosamide from CDC; interviews of 39 patients indicated that 32 recalled consuming salmon prior to their illness.

11. FDA Activity and Regulations:

For more information on recent outbreaks see the Morbidity and

Mortality Weekly Reports from CDC.

FDA is determining whether the freezing recommendations for raw or semiraw seafood with anisakid nematodes will also prevent infections with the broad fish tapeworms.

Nanophyetus spp.

- **1. Name of the Organism:** *Nanophyetus* spp.
- 2. Name of the Acute Disease:
- 3. Nature of the Acute Disease:
- 4. Diagnosis of Human Infections:
- 5. Relative Frequency of the Disease:
- 6. Associated Foods:
- 7. Usual Course of the Disease and Treatment:
- 8. Target Population:

Nanophyetus salmincola or N. schikhobalowi are the names, respectively, of the North American and Russian troglotrematoid trematodes (or flukes). These are parasitic flatworms.

Nanophyetiasis is the name of the human disease caused by these flukes. At least one newspaper referred to the disease as "fish flu." *N. salmincola* is responsible for the transmission of *Neorickettsia helminthoeca*, which causes an illness in dogs that may be serious or even fatal.

Knowledge of nanophyetiasis is limited. The first reported cases are characterized by increase of bowel movements or diarrhea, usually accompanied by increased numbers of circulating eosinophils, abdominal discomfort and nausea. A few patients reported weight loss and fatigue; some were asymptomatic. The rickettsia, though fatal to 80% of untreated dogs, is not known to infect humans.

Detection of operculate eggs of the characteristic size and shape in the feces is indicative of nanophyetiasis. The eggs are difficult to distinguish from those of *Diphyllobothrium latum*.

There have been no reported outbreaks of nanophyetiasis in North America; the only scientific reports are of 20 individual cases referred to in one Oregon clinic. A report in the popular press indicates that the frequency is significantly higher. It is significant that two cases occurred in New Orleans well outside the endemic area. In Russia's endemic area the infection rate is reported to be greater than 90% and the size of the endemic area is growing.

Nanophyetiasis is transmitted by the larval stage (metacercaria) of a worm that encysts in the flesh of freshwater fishes. In anadromous fish, the parasite's cysts can survive the period spent at sea. Although the metacercaria encysts in many species of fish, North American cases were all associated with salmonids. Raw, underprocessed, and smoked salmon and steelhead were implicated in the cases to date.

Mebendazole was ineffective as a treatment; patients kept shedding eggs, and symptoms gradually decreased over 2 months or more. Treatment with two doses of bithionol or three doses of niclosamide resulted in the resolution of symptoms and disappearance of eggs in feces. These drugs are available in the U.S. from the Centers for Disease Control's Parasitic Drug Service.

Consumers of raw or underprocessed freshwater or anadromous fish, especially salmonids.

9. Analysis of Foods:

There are no tested methods for detection of *Nanophyetus* spp. in fishes. Candling with the aid of a dissecting microscope, or pepsin HCl digestion should detect heavily infected fish.

None

10. Selected Outbreaks:

For more information on recent outbreaks see the <u>Morbidity</u> and <u>Mortality Weekly Reports</u> from CDC.

11. FDA Activity and Regulations:FDA has no specific regulation or activity regarding these trematodes. As pathogens, however, they should not be live in fish consumed raw or semiraw

Back to Parasite List

consumed raw or semiraw.

Eustrongylides sp.

1. Name of the Organism: *Eustrongylides* sp.

Larval *Eustrongylides* sp. are large, bright red roundworms (nemotodes), 25-150 mm long, 2 mm in diameter. They occur in freshwater fish, brackish water fish and in marine fish. The larvae normally mature in wading birds such as herons, egrets, and flamingos.

2. Nature of the Acute Disease:

If the larvae are consumed in undercooked or raw fish, they can attach to the wall of the digestive tract. In the five cases for which clinical symptoms have been reported, the penetration into the gut wall was accompanied by severe pain. The nematodes can perforate the gut wall and probably other organs. Removal of the nematodes by surgical resection or fiber optic devices with forceps is possible if the nematodes penetrate accessible areas of the gut.

3. Infective Dose:

One live larva can cause an infection.

4. Diagnosis of Human Illness:

In three of the five reported cases, the worms were diagnosed by surgical resection of the intestine. In one case, there was no clinical data and in one other, the patient was treated medically and recovered in 4 days.

5. Associated Foods:

Fish from fresh, brackish or salt water.

6. Relative Frequency of Disease:

The disease is extremely rare; there have been only five cases reported in the U.S.

7. Complications:

Septicemia, which is due to the perforated digestive tract.

8. Target Populations:

Those consuming whole minnows are at greatest risk. One case was reported from the consumption of sashimi.

9. Food Analysis:

These large worms may be seen without magnification in the flesh of fish and are normally very active after death of the fish.

10. Selected Outbreaks:

There have been no major outbreaks.

For more information on recent outbreaks see the Morbidity and Mortality Weekly Reports from CDC.

11. FDA Regulation or Activity:

FDA has no specific regulation or activity regarding these worms; however, as pathogens, no live *Eustrongylides* sp. should be present in fish consumed raw or semiraw.

Acanthamoeba spp., *Naegleria fowleri* and other amobae

1. Name of the Organisms:

Acanthamoeba spp., Naegleria fowleri and other amobae Members of the two genera named above are the principal examples of protozoa commonly referred to as pathogenic free-living amoebae.

2. Disease Name:

Primary amoebic meningoencephalitis (PAM), <u>Naegleria fowleri</u> and granulomatious amoebic encephalitis (GAE), <u>acanthamoebic keratitis</u> or acanthamoebic uveitis.

These organisms are ubiquitous in the environment, in soil, water, and air. Infections in humans are rare and are acquired through water entering the nasal passages (usually during swimming) and by inhalation. They are discussed here because the FDA receives inquiries about them.

PAM occurs in persons who are generally healthy prior to infection. Central nervous system involvement arises from organisms that penetrate the nasal passages and enter the brain through the cribriform plate. The organisms can multiply in the tissues of the central nervous system and may be isolated from spinal fluid. In untreated cases death occurs within 1 week of the onset of symptoms. Amphotercin B is effective in the treatment of PAM. At least four patients have recovered when treated with Amphotercin B alone or in combination with micronazole administered both intravenously and intrathecally or intraventrically.

3. Nature of the Acute Disease:

GAE occurs in persons who are immunodeficient in some way; the organisms cause a granulomatous encephalitis that leads to death in several weeks to a year after the appearance of symptoms. The primary infection site is thought to be the lungs, and the organisms in the brain are generally associated with blood vessels, suggesting vascular dissemination. Treatment with sulfamethazine may be effective in controlling the amobae.

Prior to 1985 amoebae had been reported isolated from diseased eyes only rarely; cases were associated with trauma to the eye. In 1985-1986, 24 eye cases were reported to CDC and most of these occurred in wearers of contact lenses. It has been demonstrated that many of these infections resulted from the use of home-made saline solutions with the contact lenses. Some of the lenses had been heat treated and others had been chemically disinfected. The failure of the heat treatment was attributed to faulty equipment, since the amoebae are killed by 65°C (149°F) for 30 minutes. The failure of the chemical disinfection resulted from insufficient treatment or rinsing the lenses in contaminated saline after disinfection. The following agents have been used to successfully eliminate the amoebic infection in the eye: ketoconazole, microconazole, and propamidine isothionate; however, penetrating keratoplasty has been necessary to restore useful vision.

4. Diagnosis of Human Illness:

PAM is diagnosed by the presence of amoebae in the spinal fluid. GAE is diagnosed by biopsy of the lesion. Ocular amoebic keratitis may be diagnosed by culturing corneal scrapings on nonnutrient agar overlaid with viable Escherichia coli; amoebae from PAM and GAE may be cultured by the same method. Clinical diagnosis by experienced practitioners is based on the characteristic stromal infiltrate.

5. Transmission:

6. Frequency of Infections:

7. Complications:

8. Target Populations:

9. Food Analysis:

10. Selected Outbreaks:

11. FDA Activity and Regulations:

Transmission is through water based fluids or the air.

PAM and GAE are rare in occurrence; fewer than 100 cases have been reported in the United States in the 25 years since these diseases were recognized.

PAM and GAE both lead to death in most cases. Eye infections may lead to blindness.

Immunodeficients, especially those infected with HIV, may be at risk for atypical infections. PAM, GAE, and eye infections have occurred in otherwise healthy individuals.

Foods are not analyzed for these amoebae since foods are not implicated in the infection of individuals.

These diseases are known only from isolated cases.

For more information on recent outbreaks see the <u>Morbidity and Mortality</u> <u>Weekly Reports</u> from CDC.

Since infection is not known to be by way of the digestive tract, the FDA has no regulations concerning these organisms. Eye infections are indirectly regulated by FDA's Center for Medical Devices and Radiological Health; FDA's Center for Drug Evaluation and Research regulates heat sterilization units and saline solutions for ophthalmological use. FDA has published a paper documenting the presence of amoebae in eye wash stations, and warning about the potential danger of such contamination.

Ascaris lumbricoides and Trichuris trichiura

1. Name of the Organisms:

Ascaris lumbricoides and Trichuris trichiura

2. Name of Acute Disease:

3. Nature of the Acute Disease:

4. Diagnosis of Human Illness:

5. Associated Foods:

6. Relative Frequency of Disease:

7. Usual Course of

Humans worldwide are infected with *Ascaris lumbricoides* and *Trichuris trichiura*; the eggs of these roundworms (<u>nematode</u>) are "sticky" and may be carried to the mouth by hands, other body parts, fomites (inanimate objects), or foods.

Ascariasis and trichuriasis are the scientific names of these infections. Ascariasis is also known commonly as the "large roundworm" infection and trichuriasis as "whip worm" infection.

Infection with one or a few Ascaris sp. may be inapparent unless noticed when passed in the feces, or, on occasion, crawling up into the throat and trying to exit through the mouth or nose. Infection with numerous worms may result in a pneumonitis during the migratory phase when larvae that have hatched from the ingested eggs in the lumen of the small intestine penetrate into the tissues and by way of the lymph and blood systems reach the lungs. In the lungs, the larvae break out of the pulmonary capillaries into the air sacs, ascend into the throat and descend to the small intestine again where they grow, becoming as large as 31 X 4 cm. Molting (ecdysis) occurs at various points along this path and, typically for roundworms, the male and female adults in the intestine are 5th-stage nematodes. Vague digestive tract discomfort sometimes accompanies the intestinal infection, but in small children with more than a few worms there may be intestinal blockage because of the worms' large size. Not all larval or adult worms stay on the path that is optimal for their development; those that wander may locate in diverse sites throughout the body and cause complications. Chemotherapy with anthelmintics is particularly likely to cause the adult worms in the intestinal lumen to wander; a not unusual escape route for them is into the bile duct, which they may occlude. The larvae of ascarid species that mature in hosts other than humans may hatch in the human intestine and are especially prone to wander; they may penetrate into tissues and locate in various organ systems of the human body, perhaps eliciting a fever and diverse complications.

Trichuris sp. larvae do not migrate after hatching but molt and mature in the intestine. Adults are not as large as *A. lumbricoides*. Symptoms range from inapparent through vague digestive tract distress to emaciation with dry skin and diarrhea (usually mucoid). Toxic or allergic symptoms may also occur.

Both infections are diagnosed by finding the typical eggs in the patient's feces; on occasion the larval or adult worms are found in the feces or, especially for *Ascaris* sp., in the throat, mouth, or nose.

The eggs of these worms are found in insufficiently treated sewage-fertilizer and in soils where they embryonate (i.e., larvae develop in fertilized eggs). The eggs may contaminate crops grown in soil or fertilized with sewage that has received nonlethal treatment; humans are infected when such produce is consumed raw. Infected foodhandlers may contaminate a wide variety of foods.

These infections are cosmopolitan, but ascariasis is more common in North America and trichuriasis in Europe. Relative infection rates on other continents are not available.

Both infections may self-cure after the larvae have matured into adults or may require

Disease and Complications:

symptoms (especially but not exclusively of the asthmatic sort) are common in longlasting infections or upon reinfection in ascariasis.

Particularly consumers of uncooked vegetables and fruits grown in or near soil

8. Target Populations:

Particularly consumers of uncooked vegetables and fruits grown in or near soil fertilized with sewage.

9. Analysis of Foods:

Eggs of *Ascaris* spp. have been detected on fresh vegetables (cabbage) sampled by FDA. Methods for the detection of *Ascaris* spp. and *Trichuris* spp. eggs are detailed in the FDA's <u>Bacteriological Analytical Manual</u>.

anthelmintic treatment. In severe cases, surgical removal may be necessary. Allergic

10. Selected Outbreaks:

Although no major outbreaks have occurred, there are many individual cases. The occurrence of large numbers of eggs in domestic municipal sewage implies that the infection rate, especially with *A. lumbricoides*, is high in the U.S.

11. FDA Activity and Regulations:

For more information on recent outbreaks see the Morbidity and Mortality Weekly Reports from CDC.

Ascarids and trichurids are considered pathogens and foods eaten without further cooking should not be contaminated with viable embryonated eggs of either genus.

Natural Toxins

Objectives

At the completion of this section, participants will be able to:

- Discuss some of the more common naturally occurring toxins associated with marine organisms.
- Discuss some of the more common naturally occurring toxins found in agricultural products

Introduction

Up to this point, microbiological hazards associated with food products has been discussed. But not all food hazards are directly caused by microorganisms, some are chemical hazards that are caused by byproducts from microorganisms or that occur naturally in the food source.

The natural toxins discussed in this section include:

- Ciguatera poisoning
- Shellfish toxins (PSP, DSP, NSP, ASP)
- Scombroid poisoning
- Tetrodotoxin (Pufferfish)
- Mushroom toxins
- Aflatoxins
- Pyrrolizidine alkaloids
- Phytohaemagglutinin (Red kidney bean poisoning)
- Grayanotoxin (Honey intoxication)

Marine Toxins

In fish, naturally occurring marine toxins present some unique food hazards. We need to be concerned with these toxins. The toxins found in fish are some of the most poisonous substances found on earth. Some are toxic at extremely low levels. In addition, many are heat stable and not normally destroyed by cooking. These toxins can be detected, but not easily. The presence of these toxins is usually detectable only through involved analytical methods. The affected fish look, smell, and often taste normal.

Special attention needs to be paid to a group of seafood products called molluscan shellfish. Those include oysters, mussels, and clams. There are specific toxins that are associated with this group of filter feeders. The toxins that have been involved in human illnesses caused by shellfish poisonings include: Paralytic Shellfish Poisoning or PSP; Diarrhetic Shellfish Poisoning or DSP, Neurotoxic Shellfish Poisoning or NSP, and Amnesiac Shellfish Poisoning or ASP.

Various Shellfish-Associated Toxins

1. Name of Toxins: Various Shellfish-Associated Shellfish poisoning is caused by a group of toxins elaborated by planktonic algae (dinoflagellates, in most cases) upon which the shellfish feed. The toxins are accumulated and sometimes metabolized by the shellfish. The 20 toxins responsible for paralytic shellfish poisonings (PSP) are all derivatives of saxitoxin. Diarrheic shellfish poisoning (DSP) is presumably caused by a group of high molecular weight polyethers, including okadaic acid, the dinophysis toxins, the pectenotoxins, and yessotoxin. Neurotoxic shellfish poisoning (NSP) is the result of exposure to a group of polyethers called brevetoxins. Amnesic shellfish poisoning (ASP) is caused by the unusual amino acid, domoic acid, as the contaminant of shellfish.

Shellfish Poisoning:

2. Name of the Acute Diseases:

Paralytic Shellfish Poisoning (PSP), Diarrheic Shellfish Poisoning (DSP), Neurotoxic Shellfish Poisoning (NSP), Amnesic Shellfish Poisoning (ASP).

Ingestion of contaminated shellfish results in a wide variety of symptoms, depending upon the toxins(s) present, their concentrations in the shellfish and the amount of contaminated shellfish consumed. In the case of PSP, the effects are predominantly neurological and include tingling, burning, numbness, drowsiness, incoherent speech, and respiratory paralysis. Less well characterized are the symptoms associated with DSP, NSP, and ASP. DSP is primarily observed as a generally mild gastrointestinal disorder, i.e., nausea, vomiting, diarrhea, and abdominal pain accompanied by chills, headache, and fever. Both gastrointestinal and neurological symptoms characterize NSP, including tingling and numbness of lips, tongue, and throat, muscular aches, dizziness, reversal of the sensations of hot and cold, diarrhea, and vomiting. ASP is characterized by gastrointestinal disorders (vomiting, diarrhea, abdominal pain) and neurological problems (confusion, memory loss, disorientation, seizure, coma).

3. Nature of the Diseases:

PSP: Symptoms of the disease develop fairly rapidly, within 0.5 to 2 hours after ingestion of the shellfish, depending on the amount of toxin consumed. In severe cases respiratory paralysis is common, and death may occur if respiratory support is not provided. When such support is applied within 12 hours of exposure, recovery usually is complete, with no lasting side effects. In unusual cases, because of the weak hypotensive action of the toxin, death may occur from cardiovascular collapse despite respiratory support.

4. Normal Course of the Disease:

NSP: Onset of this disease occurs within a few minutes to a few hours; duration is fairly short, from a few hours to several days. Recovery is complete with few after effects; no fatalities have been reported.

DSP: Onset of the disease, depending on the dose of toxin ingested, may be as little as 30 minutes to 2 to 3 hours, with symptoms of the illness lasting as long as 2 to 3 days. Recovery is complete with no after effects; the disease is generally not life threatening.

symptoms within 24 hours; neurological symptoms occur within 48 hours. The toxicosis is particularly serious in elderly patients, and includes symptoms reminiscent of Alzheimer's disease. All fatalities to date have involved elderly patients.

Diagnosis of shellfish poisoning is based entirely on observed

Diagnosis of shellfish poisoning is based entirely on observed symptomatology and recent dietary history.

ASP: The toxicosis is characterized by the onset of gastrointestinal

All shellfish (filter-feeding molluscs) are potentially toxic. However, PSP is generally associated with mussels, clams, cockles, and scallops; NSP with shellfish harvested along the Florida coast and the Gulf of Mexico; DSP with mussels, oysters, and scallops, and ASP with mussels.

Good statistical data on the occurrence and severity of shellfish poisoning are largely unavailable, which undoubtedly reflects the inability to measure the true incidence of the disease. Cases are frequently misdiagnosed and, in general, infrequently reported. Of these toxicoses, the most serious from a public health perspective appears to be PSP. The extreme potency of the PSP toxins has, in the past, resulted in an unusually high mortality rate.

All humans are susceptible to shellfish poisoning. Elderly people are apparently predisposed to the severe neurological effects of the ASP toxin. A disproportionate number of PSP cases occur among tourists or others who are not native to the location where the toxic shellfish are harvested. This may be due to disregard for either official quarantines or traditions of safe consumption, both of which tend to protect the local population.

The mouse bioassay has historically been the most universally applied technique for examining shellfish (especially for PSP); other bioassay procedures have been developed but not generally applied. Unfortunately, the dose-survival times for the DSP toxins in the mouse assay fluctuate considerably and fatty acids interfere with the assay. giving false-positive results; consequently, a suckling mouse assay that has been developed and used for control of DSP measures fluid accumulation after injection of the shellfish extract. In recent years considerable effort has been applied to development of chemical assays to replace these bioassays. As a result a good high performance liquid chromatography (HPLC) procedure has been developed to identify individual PSP toxins (detection limit for saxitoxin = 20 fg/100 g of meats; 0.2 ppm), an excellent HPLC procedure (detection limit for okadaic acid = 400 ng/g; 0.4 ppm), a commercially available immunoassay (detection limit for okadaic acid = 1 fg/100 g of meats; 0.01 ppm) for DSP and a totally satisfactory HPLC procedure for ASP (detection limit for domoic acid = 750 ng/g; 0.75 ppm).

5. Diagnosis of Human Illnesses:

6. Associated Foods:

7. Relative Frequency of Disease:

8. Target Populations:

9. Analysis of Foods:

PSP is associated with relatively few outbreaks, most likely because of the strong control programs in the United States that prevent human exposure to toxic shellfish. That PSP can be a serious public health problem, however, was demonstrated in Guatemala, where an outbreak of 187 cases with 26 deaths, recorded in 1987, resulted from ingestion of a clam soup. The outbreak led to the establishment of a control program over shellfish harvested in Guatemala. ASP first came to the attention of public health authorities in 1987 when 156 cases of acute intoxication occurred as a result of ingestion of cultured blue mussels (Mytilus edulis) harvested off Prince Edward Island, in eastern Canada; 22 individuals were hospitalized and three elderly patients eventually died.

The occurrence of DSP in Europe is sporadic, continuous and presumably widespread (anecdotal). DSP poisoning has not been confirmed in U.S. seafood, but the organisms that produce DSP are present in U.S. waters. An outbreak of DSP was recently confirmed in Eastern Canada. Outbreaks of NSP are sporadic and continuous along the Gulf coast of Florida and were recently reported in North Carolina and Texas.

For more information on recent outbreaks see the **Morbidity and Mortality Weekly Reports** from CDC.

Back to Natural Toxin List

Ciguatera

1. Name of Toxin: Ciguatera Ciquatera Fish Poisoning Ciguatera is a form of human poisoning caused by the consumption of subtropical and tropical marine finfish that have accumulated naturally 2. Name of Disease: occurring toxins through their diet. The toxins are known to originate from several dinoflagellate (algae) species that are common to ciguatera endemic regions in the lower latitudes. Manifestations of ciguatera in humans usually involves a combination of gastrointestinal, neurological, and cardiovascular disorders. Symptoms 3. Nature of Disease: defined within these general categories vary with the geographic origin of toxic fish. Initial signs of poisoning occur within six hours after consumption of toxic fish and include perioral numbness and tingling (paresthesia), which may spread to the extremities, nausea, vomiting, and diarrhea. Neurological signs include intensified paresthesia, arthralgia, myalgia, headache, temperature sensory reversal and acute sensitivity to temperature extremes, vertigo, and muscular weakness to the point of prostration. Cardiovascular signs include arrhythmia, bradycardia or tachycardia, and reduced blood pressure. Ciguatera poisoning is 4. Normal Course of Disease: usually self-limiting, and signs of poisoning often subside within several days from onset. However, in severe cases the neurological symptoms are known to persist from weeks to months. In a few isolated cases neurological symptoms have persisted for several years, and in other cases recovered patients have experienced recurrence of neurological symptoms months to years after recovery. Such relapses are most often associated with changes in dietary habits or with consumption of alcohol. There is a low incidence of death resulting from respiratory and cardiovascular failure. Clinical testing procedures are not presently available for the diagnosis of ciguatera in humans. Diagnosis is based entirely on symptomology and recent dietary history. An enzyme immunoassay (EIA) designed to 5. Diagnosis of Human Illness: detect toxic fish in field situations is under evaluation by the Association of Official Analytical Chemists (AOAC) and may provide some measure of protection to the public in the future. Marine finfish most commonly implicated in ciguatera fish poisoning include the groupers, barracudas, snappers, jacks, mackerel, and 6. Associated Foods: triggerfish. Many other species of warm-water fishes harbor ciguatera toxins. The occurrence of toxic fish is sporadic, and not all fish of a given species or from a given locality will be toxic. The relative frequency of ciguatera fish poisoning in the United States is not known. The disease has only recently become known to the 7. Relative Frequency of Disease: general medical community, and there is a concern that incidence is largely under-reported because of the generally non-fatal nature and

short duration of the disease.

All humans are believed to be susceptible to ciguatera toxins.

Populations in tropical/subtropical regions are most likely to be affected because of the frequency of exposure to toxic fishes. However, the

8. Target Population:

9. Analysis of Foods:

expanded the geographic range of human poisonings.

The ciguatera toxins can be recovered from toxic fish through tedious

extraction and purification procedures. The mouse bioassay is a generally accepted method of establishing toxicity of suspect fish. A much simplified EIA method intended to supplant the mouse bioassay for identifying ciguatera toxins is under evaluation.

increasing per capita consumption of fishery products coupled with an increase in interregional transportation of seafood products has

Isolated cases of ciguatera fish poisoning have occurred along the eastern coast of the United States from south Florida to Vermont. Hawaii, the U.S. Virgin Islands, and Puerto Rico experience sporadic cases with some regularity. A major outbreak of ciguatera occurred in Puerto Rico between April and June 1981 in which 49 persons were afflicted and two fatalities occurred. This outbreak prompted government officials of the Commonwealth of Puerto Rico to ban the sale of barracuda, amberjack, and blackjack.

In February-March of 1987 a large common-source outbreak of ciguatera occurred among Canadian vacationers returning from a Caribbean resort. Of 147 tourists, 61 ate a fish casserole shortly before departure, resulting in 57 identified cases of ciguatera.

In May of 1988 several hundred pounds of fish (primarily hogfish) from the Dry Tortuga Bank were responsible for over 100 human poisonings in Palm Beach County, Florida. The fish were sold to a seafood distributor after the fishermen (sport spearfishermen) themselves were first afflicted but dismissed their illness as seasickness and hangover. The poisonings resulted in a statewide warning against eating hogfish, grouper, red snapper, amberjack, and barracuda caught at the Dry Tortuga Bank.

For a report on Ciguatera poisoning in Florida, see this MMWR 42(21):1993 Jun 04.

For more information on recent outbreaks see the **Morbidity and Mortality Weekly Reports** from CDC.

Back to Natural Toxin List

10. Selected Outbreaks:

Scombrotoxin

Scombrotoxin

1. Name of Toxin:

Scombroid Poisoning (also called Histamine Poisoning) Scombroid poisoning is caused by the ingestion of foods that contain high levels of histamine and possibly other vasoactive amines and compounds. Histamine and other amines are formed by the growth of certain bacteria and the subsequent action of their decarboxylase 2. Name of Acute Disease: enzymes on histidine and other amino acids in food, either during the production of a product such as Swiss cheese or by spoilage of foods such as fishery products, particularly tuna or mahi mahi. However, any food that contains the appropriate amino acids and is subjected to certain bacterial contamination and growth may lead to scombroid poisoning when ingested. Initial symptoms may include a tingling or burning sensation in the mouth, a rash on the upper body and a drop in blood pressure. Frequently, headaches and itching of the skin are encountered. The 3. Nature of Disease: symptoms may progress to nausea, vomiting, and diarrhea and may require hospitalization, particularly in the case of elderly or impaired patients. The onset of intoxication symptoms is rapid, ranging from immediate to 4. Normal Course of Disease: 30 minutes. The duration of the illness is usually 3 hours, but may last several days. Diagnosis of the illness is usually based on the patient's symptoms, time of onset, and the effect of treatment with antihistamine medication. 5. Diagnosis of Human Illness: The suspected food must be analyzed within a few hours for elevated levels of histamine to confirm a diagnosis. Fishery products that have been implicated in scombroid poisoning include the tunas (e.g., skipjack and yellowfin), mahi mahi, bluefish, sardines, mackerel, amberjack, and abalone. Many other products also have caused the toxic effects. The primary cheese involved in intoxications has been Swiss cheese. The toxin forms in a food when certain bacteria are present and time and temperature permit their 6. Associated Foods: growth. Distribution of the toxin within an individual fish fillet or between cans in a case lot can be uneven, with some sections of a product causing illnesses and others not. Neither cooking, canning, or freezing reduces the toxic effect. Common sensory examination by the consumer cannot ensure the absence or presence of the toxin. Chemical testing is the only reliable test for evaluation of a product. Scombroid poisoning remains one of the most common forms of fish poisoning in the United States. Even so, incidents of poisoning often go unreported because of the lack of required reporting, a lack of information by some medical personnel, and confusion with the symptoms of other illnesses. Difficulties with underreporting are a 7. Relative Frequency of Disease: worldwide problem. In the United States from 1968 to 1980, 103 incidents of intoxication involving 827 people were reported. For the same period in Japan, where the quality of fish is a national priority, 42 incidents involving 4,122 people were recorded. Since 1978, 2 actions by FDA have reduced the frequency of intoxications caused by specific

products. A defect action level for histamine in canned tuna resulted in

increased industry quality control. Secondly, blocklisting of mahi mahi reduced the level of fish imported to the United States. All humans are susceptible to scombroid poisoning; however, the symptoms can be severe for the elderly and for those taking medications such as isoniazid. Because of the worldwide network for harvesting, processing, and distributing fishery products, the impact of 8. Target Population: the problem is not limited to specific geographical areas of the United States or consumption pattern. These foods are sold for use in homes. schools, hospitals, and restaurants as fresh, frozen, or processed products. An official method was developed at FDA to determine histamine, using 9. Analysis of Foods: a simple alcoholic extraction and quantitation by fluorescence spectroscopy. There are other untested procedures in the literature. Several large outbreaks of scombroid poisoning have been reported. In 1970, some 40 children in a school lunch program became ill from imported canned tuna. In 1973, more than 200 consumers across the United States were affected by domestic canned tuna. In 1979-1980 more than 200 individuals became ill after consuming imported frozen mahi mahi. Symptoms varied with each incident. In the 1973 situation, of the interviewed patients, 86% experienced nausea, 55% diarrhea, 10. Selected Outbreaks: 44% headaches and 32% rashes. Other incidents of intoxication have resulted from the consumption of canned abalone-like products, canned anchovies, and fresh and frozen amberjack, bluefish sole, and scallops. In particular, shipments of unfrozen fish packed in refrigerated containers have posed a significant problem because of inadequate temperature control. For more information on recent outbreaks see the Morbidity and Mortality Weekly Reports from CDC.

5. Diagnosis of Human Illness:

6. Associated Foods:

Tetrodotoxin (anhydrotetrodotoxin 4-epitetrodotoxin, tetrodonic acid)

Pufferfish Poisoning, Tetradon Poisoning, Fugu Poisoning

Fish poisoning by consumption of members of the order Tetraodontiformes is one of the most violent intoxications from marine species. The gonads, liver, intestines, and skin of pufferfish can contain levels of tetrodotoxin sufficient to produce rapid and violent death. The flesh of many pufferfish may not usually be dangerously toxic. Tetrodotoxin has also been isolated from widely differing animal species, including the California newt, parrotfish, frogs of the genus Atelopus, the blue-ringed octopus, starfish, angelfish, and xanthid crabs. The metabolic source of tetrodotoxin is uncertain. No algal source has been identified, and until recently tetrodotoxin was assumed to be a metabolic product of the host. However, recent reports of the production of tetrodotoxin/anhydrotetrodotoxin by several bacterial species, including strains of the family Vibrionaceae, Pseudomonas sp., and Photobacterium phosphoreum, point toward a bacterial origin of this family of toxins. These are relatively common marine bacteria that are often associated with marine animals. If confirmed, these findings may have some significance in toxicoses that have been more directly related to these bacterial species.

The first symptom of intoxication is a slight numbness of the lips and tongue, appearing between 20 minutes to three hours after eating poisonous pufferfish. The next symptom is increasing paraesthesia in the face and extremities, which may be followed by sensations of lightness or floating. Headache, epigastric pain, nausea, diarrhea, and/or vomiting may occur. Occasionally, some reeling or difficulty in walking may occur. The second stage of the intoxication is increasing paralysis. Many victims are unable to move; even sitting may be difficult. There is increasing respiratory distress. Speech is affected, and the victim usually exhibits dyspnea, cyanosis, and hypotension. Paralysis increases and convulsions, mental impairment, and cardiac arrhythmia may occur. The victim, although completely paralyzed, may be conscious and in some cases completely lucid until shortly before death. Death usually occurs within 4 to 6 hours, with a known range of about 20 minutes to 8 hours.

The diagnosis of pufferfish poisoning is based on the observed symptomology and recent dietary history.

Poisonings from tetrodotoxin have been almost exclusively associated with the consumption of pufferfish from waters of the Indo-Pacific ocean regions. Several reported cases of poisonings, including fatalities, involved pufferfish from the Atlantic Ocean, Gulf of Mexico, and Gulf of California. There have been no confirmed cases of poisoning from the Atlantic pufferfish, Spheroides maculatus. However, in one study, extracts from fish of this species were highly toxic in mice. The trumpet shell Charonia sauliae has been implicated in food poisonings, and evidence suggests that it contains a tetrodotoxin derivative. There have been several reported poisonings from mislabelled pufferfish and at least one report of a fatal episode when an individual swallowed a California newt.

10. Selected Outbreaks:

9. Analysis of Foods:

From 1974 through 1983 there were 646 reported cases of pufferfish poisoning in Japan, with 179 fatalities. Estimates as high as 200 cases per year with mortality approaching 50% have been reported. Only a few cases have been reported in the United States, and outbreaks in countries outside the Indo-Pacific area are rare.

All humans are susceptible to tetrodotoxin poisoning. This toxicosis may be avoided by not consuming pufferfish or other animal species containing tetrodotoxin. Most other animal species known to contain tetrodotoxin are not usually consumed by humans. Poisoning from tetrodotoxin is of major public health concern primarily in Japan, where "fugu" is a traditional delicacy. It is prepared and sold in special restaurants where trained and licensed individuals carefully remove the viscera to reduce the danger of poisoning. Importation of pufferfish into the United States is not generally permitted, although special exceptions may be granted. There is potential for misidentification and/or mislabeling, particularly of prepared, frozen fish products.

The mouse bioassay developed for <u>paralytic shellfish poisoning</u> (PSP) can be used to monitor tetrodotoxin in pufferfish and is the current method of choice. An HPLC method with post-column reaction with alkali and fluorescence has been developed to determine tetrodotoxin and its associated toxins. The alkali degradation products can be confirmed as their trimethylsilyl derivatives by gas chromatography/mass spectrometry. These chromatographic methods have not yet been validated.

Pufferfish poisoning is a continuing problem in Japan, affecting 30 - 100 persons/year. Most of these poisoning episodes occur from home preparation and consumption and not from commercial sources of the pufferfish. Three deaths were reported in Italy in 1977 following the consumption of frozen pufferfish imported from Taiwan and mislabelled as angler fish.

An incident of Fugu fish poisoning in the United States is reported in MMWR 45(19):1996 May 17.

For more information on recent outbreaks see the **Morbidity and Mortality Weekly Reports** from CDC.

Back to Natural Toxin List

Agricultural Toxins

In addition to the toxins found in marine species there are naturally occurring toxins that are found in agricultural commodities. In general, these toxins are grouped under the heading of mycotoxins. Mycotoxins are produced by fungi, which wide spread in nature and therefore has the potential for appearing in most types of agricultural commodities.

Not all fungus are toxic, and those that are only produce toxin if environmental conditions like water activity, temperature, availability of oxygen and other conditions are right. If all the conditions are correct, they can enter the foods directly, for example as a result of growth on a cereal grain like corn or wheat. Mycotoxins can also enter the food chain indirectly as a result of using a contaminated food ingredient for animal food. In that instance, the mycotoxins may be passed on into animal products like milk and cheese.

Aflatoxins

1. Name of Toxin:

Aflatoxins

Aflatoxicosis

2. Name of Acute Disease:

3. Nature of Disease:

4. Normal Course of Disease:

Aflatoxicosis is poisoning that results from ingestion of aflatoxins in contaminated food or feed. The aflatoxins are a group of structurally related toxic compounds produced by certain strains of the fungi Aspergillus flavus and A. parasiticus. Under favorable conditions of temperature and humidity, these fungi grow on certain foods and feeds, resulting in the production of aflatoxins. The most pronounced contamination has been encountered in tree nuts, peanuts, and other oilseeds, including corn and cottonseed. The major aflatoxins of concern are designated B1, B2, G1, and G2. These toxins are usually found together in various foods and feeds in various proportions; however, aflatoxin B1 is usually predominant and is the most toxic. When a commodity is analyzed by thin-layer chromatography, the aflatoxins separate into the individual components in the order given above; however, the first two fluoresce blue when viewed under ultraviolet light and the second two fluoresce green. Aflatoxin M a major metabolic product of aflatoxin B1 in animals and is usually excreted in the milk and urine of dairy cattle and other mammalian species that have consumed aflatoxin-contaminated food or feed.

Aflatoxins produce acute necrosis, cirrhosis, and carcinoma of the liver in a number of animal species; no animal species is resistant to the acute toxic effects of aflatoxins; hence it is logical to assume that humans may be similarly affected. A wide variation in LD50 values has been obtained in animal species tested with single doses of aflatoxins. For most species, the LD50 value ranges from 0.5 to 10 mg/kg body weight. Animal species respond differently in their susceptibility to the chronic and acute toxicity of aflatoxins. The toxicity can be influenced by environmental factors, exposure level, and duration of exposure. age, health, and nutritional status of diet. Aflatoxin B1 is a very potent carcinogen in many species, including nonhuman primates, birds, fish, and rodents. In each species, the liver is the primary target organ of acute injury. Metabolism plays a major role in determining the toxicity of aflatoxin B1: studies show that this aflatoxion requires metabolic activation to exert its carcinogenic effect, and these effects can be modified by induction or inhibition of the mixed function oxidase system.

In well-developed countries, aflatoxin contamination rarely occurs in foods at levels that cause acute aflatoxicosis in humans. In view of this, studies on human toxicity from ingestion of aflatoxins have focused on their carcinogenic potential. The relative susceptibility of humans to aflatoxins is not known, even though epidemiological studies in Africa and Southeast Asia, where there is a high incidence of hepatoma, have revealed an association between cancer incidence and the aflatoxin content of the diet. These studies have not proved a cause-effect relationship, but the evidence suggests an association.

One of the most important accounts of aflatoxicosis in humans occurred in more than 150 villages in adjacent districts of two neighboring states in northwest India in the fall of 1974. According to one report of this

outbreak, 397 persons were affected and 108 persons died. In this outbreak, contaminated corn was the major dietary constituent, and aflatoxin levels of 0.25 to 15 mg/kg were found. The daily aflatoxin B1 intake was estimated to have been at least 55 ug/kg body weight for an undetermined number of days. The patients experienced high fever, rapid progressive jaundice, edema of the limbs, pain, vomiting, and swollen livers. One investigator reported a peculiar and very notable feature of the outbreak: the appearance of signs of disease in one village population was preceded by a similar disease in domestic dogs, which was usually fatal. Histopathological examination of humans showed extensive bile duct proliferation and periportal fibrosis of the liver together with gastrointestinal hemorrhages. A 10-year follow-up of the Indian outbreak found the survivors fully recovered with no ill effects from the experience.

A second outbreak of aflatoxicosis was reported from Kenya in 1982. There were 20 hospital admissions with a 60% mortality; daily aflatoxin intake was estimated to be at least 38 ug/kg body weight for an undetermined number of days.

In a deliberate suicide attempt, a laboratory worker ingested 12 ug/kg body weight of aflatoxin B1 per day over a 2-day period and 6 months later, 11 ug/kg body weight per day over a 14-day period. Except for transient rash, nausea and headache, there were no ill effects; hence, these levels may serve as possible no-effect levels for aflatoxin B1 in humans. In a 14-year follow-up, a physical examination and blood chemistry, including tests for liver function, were normal.

Aflatoxicosis in humans has rarely been reported; however, such cases are not always recognized. Aflatoxicosis may be suspected when a disease outbreak exhibits the following characteristics:

the cause is not readily identifiable

the condition is not transmissible

syndromes may be associated with certain batches of food treatment with antibiotics or other drugs has little effect

the outbreak may be seasonal, i.e., weather conditions may affect mold growth.

The adverse effects of aflatoxins in animals (and presumably in humans) have been categorized in two general forms.

A. (Primary) Acute aflatoxicosis is produced when moderate to high levels of aflatoxins are consumed. Specific, acute episodes of disease ensue may include hemorrhage, acute liver damage, edema, alteration in digestion, absorption and/or metabolism of nutrients, and possibly death.

B. (Primary) Chronic aflatoxicosis results from ingestion of low to moderate levels of aflatoxins. The effects are usually subclinical and difficult to recognize. Some of the common symptoms are impaired food conversion and slower rates of growth with or without the production of an overt aflatoxin syndrome.

In the United States, aflatoxins have been identified in corn and corn products, peanuts and peanut products, cottonseed, milk, and tree nuts such as Brazil nuts, pecans, pistachio nuts, and walnuts. Other grains and nuts are susceptible but less prone to contamination.

The relative frequency of aflatoxicosis in humans in the United States is not known. No outbreaks have been reported in humans. Sporadic

5. Diagnosis of Human Illnesses:

7. Associated Foods:

8. Relative Frequency of Disease:

cases have been reported in animals. Although humans and animals are susceptible to the effects of acute aflatoxicosis, the chances of human exposure to acute levels of 9. Target Populations: aflatoxin is remote in well-developed countries. In undeveloped countries, human susceptibility can vary with age, health, and level and duration of exposure. Many chemical procedures have been developed to identify and measure aflatoxins in various commodities. The basic steps include extraction, lipid removal, cleanup, separation and quantification. Depending on the nature of the commodity, methods can sometimes be simplified by omitting unnecessary steps. Chemical methods have 9. Analysis of Foods: been developed for peanuts, corn, cottonseed, various tree nuts, and animal feeds. Chemical methods for aflatoxin in milk and dairy products are far more sensitive than for the above commodities because the aflatoxin M animal metabolite is usually found at much lower levels (ppb and ppt). All collaboratively studied methods for aflatoxin analysis are described in Chapter 26 of the AOAC Official Methods of Analysis. Very little information is available on outbreaks of aflatoxicosis in humans because medical services are less developed in the areas of 10. Outbreaks: the world where high levels of contamination of aflatoxins occur in foods, and, therefore, many cases go unnoticed. For more information on recent outbreaks see the Morbidity and Mortality Weekly Reports from CDC.

Mushroom toxins

1. Name of Toxin(s):

Amanitin, Gyromitrin, Orellanine, Muscarine, Ibotenic Acid, Muscimol, Psilocybin, Coprine

Mushroom Poisoning, Toadstool Poisoning

Mushroom poisoning is caused by the consumption of raw or cooked fruiting bodies (mushrooms, toadstools) of a number of species of higher fungi. The term toadstool (from the German Todesstuhl, death's stool) is commonly given to poisonous mushrooms, but for individuals who are not experts in mushroom identification there are generally no easily recognizable differences between poisonous and nonpoisonous species. Old wives' tales notwithstanding, there is no general rule of thumb for distinguishing edible mushrooms and poisonous toadstools. The toxins involved in mushroom poisoning are produced naturally by the fungi themselves, and each individual specimen of a toxic species should be considered equally poisonous. Most mushrooms that cause human poisoning cannot be made nontoxic by cooking, canning, freezing, or any other means of processing. Thus, the only way to avoid poisoning is to avoid consumption of the toxic species. Poisonings in the United States occur most commonly when hunters of wild mushrooms (especially novices) misidentify and consume a toxic species, when recent immigrants collect and consume a poisonous American species that closely resembles an edible wild mushroom from their native land, or when mushrooms that contain psychoactive compounds are intentionally consumed by persons who desire these effects.

Mushroom poisonings are generally acute and are manifested by a variety of symptoms and prognoses, depending on the amount and species consumed. Because the chemistry of many of the mushroom toxins (especially the less deadly ones) is still unknown and positive identification of the mushrooms is often difficult or impossible, mushroom poisonings are generally categorized by their physiological effects. There are four categories of mushroom toxins: protoplasmic poisons (poisons that result in generalized destruction of cells, followed by organ failure); neurotoxins (compounds that cause neurological symptoms such as profuse sweating, coma, convulsions, hallucinations, excitement, depression, spastic colon); gastrointestinal irritants (compounds that produce rapid, transient nausea, vomiting, abdominal cramping, and diarrhea); and disulfiram-like toxins. Mushrooms in this last category are generally nontoxic and produce no symptoms unless alcohol is consumed within 72 hours after eating them, in which case a short-lived acute toxic syndrome is produced.

The normal course of the disease varies with the dose and the mushroom species eaten. Each poisonous species contains one or more toxic compounds that are unique to few other species. Therefore, cases of mushroom poisonings generally do not resembles each other unless they are caused by the same or very closely related mushroom species. Almost all mushroom poisonings may be grouped in one of the categories outlined above.

2. Name of Acute Disease:

3. Nature of Disease(s):

4. Normal Course of Disease(s):

PROTOPLASMIC POISONS

Amatoxins:

Several mushroom species, including the Death Cap or Destroying Angel (Amanita phalloides, A. virosa), the Fool's Mushroom (A. verna) and several of their relatives, along with the Autumn Skullcap (Galerina autumnalis) and some of its relatives, produce a family of cyclic octapeptides called amanitins. Poisoning by the amanitins is characterized by a long latent period (range 6-48 hours, average 6-15 hours) during which the patient shows no symptoms. Symptoms appear at the end of the latent period in the form of sudden, severe seizures of abdominal pain, persistent vomiting and watery diarrhea, extreme thirst, and lack of urine production. If this early phase is survived, the patient may appear to recover for a short time, but this period will generally be followed by a rapid and severe loss of strength, prostration, and paincaused restlessness. Death in 50-90% of the cases from progressive and irreversible liver, kidney, cardiac, and skeletal muscle damage may follow within 48 hours (large dose), but the disease more typically lasts 6 to 8 days in adults and 4 to 6 days in children. Two or three days after the onset of the later phase, jaundice, cyanosis, and coldness of the skin occur. Death usually follows a period of coma and occasionally convulsions. If recovery occurs, it generally requires at least a month and is accompanied by enlargement of the liver. Autopsy will usually reveal fatty degeneration and necrosis of the liver and kidney. Hvdrazines:

Certain species of False Morel (*Gyromitra* esculenta and *G. gigas*) contain the protoplasmic poison gyromitrin, a volatile hydrazine derivative. Poisoning by this toxin superficially resembles *Amanita* poisoning but is less severe. There is generally a latent period of 6 - 10 hours after ingestion during which no symptoms are evident, followed by sudden onset of abdominal discomfort (a feeling of fullness), severe headache, vomiting, and sometimes diarrhea. The toxin affects primarily the liver, but there are additional disturbances to blood cells and the central nervous system. The mortality rate is relatively low (2-4%). Poisonings with symptoms almost identical to those produced by *Gyromitra* have also been reported after ingestion of the Early False Morel (*Verpa bohemica*). The toxin is presumed to be related to gyromitrin but has not yet been identified.

Orellanine:

The final type of protoplasmic poisoning is caused by the Sorrel Webcap mushroom (*Cortinarius orellanus*) and some of its relatives. This mushroom produces orellanine, which causes a type of poisoning characterized by an extremely long asymptomatic latent period of 3 to 14 days. An intense, burning thirst (polydipsia) and excessive urination (polyuria) are the first symptoms. This may be followed by nausea, headache, muscular pains, chills, spasms, and loss of consciousness. In severe cases, severe renal tubular necrosis and kidney failure may result in death (15%) several weeks after the poisoning. Fatty degeneration of the liver and severe inflammatory changes in the intestine accompany the renal damage, and recovery in less severe cases may require several months.

NEUROTOXINS

Poisonings by mushrooms that cause neurological problems may be divided into three groups, based on the type of symptoms produced, and named for the substances responsible for these symptoms.

Muscarine Poisoning:

Ingestion of any number of *Inocybe* or *Clitocybe* species (e.g., *Inocybe geophylla*, *Clitocybe dealbata*) results in an illness characterized primarily by profuse sweating. This effect is caused by the presence in these mushrooms of high levels (3- 4%) of <u>muscarine</u>. Muscarine poisoning is characterized by increased salivation, perspiration, and lacrimation within 15 to 30 minutes after ingestion of the mushroom. With large doses, these symptoms may be followed by abdominal pain, severe nausea, diarrhea, blurred vision, and labored breathing. Intoxication generally subsides within 2 hours. Deaths are rare, but may result from cardiac or respiratory failure in severe cases.

Ibotenic acid/Muscimol Poisoning:

The Fly Agaric (*Amanita muscaria*) and Panthercap (*Amanita pantherina*) mushrooms both produce <u>ibotenic acid</u> and <u>muscimol</u>. Both substances produce the same effects, but muscimol is approximately 5 times more potent than ibotenic acid. Symptoms of poisoning generally occur within 1 - 2 hours after ingestion of the mushrooms. An initial abdominal discomfort may be present or absent, but the chief symptoms are drowsiness and dizziness (sometimes accompanied by sleep), followed by a period of hyperactivity, excitability, illusions, and delirium. Periods of drowsiness may alternate with periods of excitement, but symptoms generally fade within a few hours. Fatalities rarely occur in adults, but in children, accidental consumption of large quantities of these mushrooms may cause convulsions, coma, and other neurologic problems for up to 12 hours.

Psilocybin Poisoning:

A number of mushrooms belonging to the genera Psilocybe, Panaeolus, Copelandia, Gymnopilus, Conocybe, and Pluteus, when ingested, produce a syndrome similar to alcohol intoxication (sometimes accompanied by hallucinations). Several of these mushrooms (e.g., Psilocybe cubensis, P. mexicana, Conocybe cyanopus) are eaten for their psychotropic effects in religious ceremonies of certain native American tribes, a practice which dates to the pre-Columbian era. The toxic effects are caused by psilocin and psilocybin. Onset of symptoms is usually rapid and the effects generally subside within 2 hours. Poisonings by these mushrooms are rarely fatal in adults and may be distinguished from ibotenic acid poisoning by the absence of drowsiness or coma. The most severe cases of psilocybin poisoning occur in small children, where large doses may cause the hallucinations accompanied by fever, convulsions, coma, and death. These mushrooms are generally small, brown, nondescript, and not particularly fleshy; they are seldom mistaken for food fungi by innocent hunters of wild mushrooms. Poisonings caused by intentional ingestion of these mushrooms by people with no legitimate religious justification must be handled with care, since the only cases likely to be seen by the physician are overdoses or intoxications caused by a combination of the mushroom and some added psychotropic substance (such as PCP).

GASTROINTESTINAL IRRITANTS

Numerous mushrooms, including the Green Gill (*Chlorophyllum molybdites*), Gray Pinkgill (*Entoloma lividum*), Tigertop (*Tricholoma pardinum*), Jack O'Lantern (*Omphalotus illudens*), Naked Brimcap (*Paxillus involutus*), Sickener (*Russula emetica*), Early False Morel (*Verpa bohemica*), Horse mushroom (*Agaricus arvensis*) and Pepper bolete (*Boletus piperatus*), contain toxins that can cause gastrointestinal

distress, including but not limited to nausea, vomiting, diarrhea, and abdominal cramps. In many ways these symptoms are similar to those caused by the deadly protoplasmic poisons. The chief and diagnostic difference is that poisonings caused by these mushrooms have a rapid onset, rather than the delayed onset seen in protoplasmic poisonings. Some mushrooms (including the first five species mentioned above) may cause vomiting and/or diarrhea which lasts for several days. Fatalities caused by these mushrooms are relatively rare and are associated with dehydration and electrolyte imbalances caused by diarrhea and vomiting, especially in debilitated, very young, or very old patients. Replacement of fluids and other appropriate supportive therapy will prevent death in these cases. The chemistry of the toxins responsible for this type of poisoning is virtually unknown, but may be related to the presence in some mushrooms of unusual sugars, amino acids, peptides, resins, and other compounds.

DISULFIRAM-LIKE POISONING

The Inky Cap Mushroom (*Coprinus atramentarius*) is most commonly responsible for this poisoning, although a few other species have also been implicated. A complicating factor in this type of intoxication is that this species is generally considered edible (i.e., no illness results when eaten in the absence of alcoholic beverages). The mushroom produces an unusual amino acid, coprine, which is converted to cyclopropanone hydrate in the human body. This compound interferes with the breakdown of alcohol, and consumption of alcoholic beverages within 72 hours after eating it will cause headache, nausea and vomiting, flushing, and cardiovascular disturbances that last for 2 - 3 hours.

MISCELLANEOUS POISONINGS

Young fruiting bodies of the sulfur shelf fungus *Laetiporus sulphureus* are considered edible. However, ingestion of this shelf fungus has caused digestive upset and other symptoms in adults and visual hallucinations and ataxia in a child.

A clinical testing procedure is currently available only for the most serious types of mushroom toxins, the amanitins. The commercially available method uses a 3H-radioimmunoassay (RIA) test kit and can detect sub-nanogram levels of toxin in urine and plasma. Unfortunately, it requires a 2-hour incubation period, and this is an excruciating delay in a type of poisoning which the clinician generally does not see until a day or two has passed. A 125I-based kit which overcomes this problem has recently been reported, but has not yet reached the clinic. A sensitive and rapid HPLC technique has been reported in the literature even more recently, but it has not yet seen clinical application. Since most clinical laboratories in this country do not use even the older RIA technique, diagnosis is based entirely on symptomology and recent dietary history. Despite the fact that cases of mushroom poisoning may be broken down into a relatively small number of categories based on symptomatology, positive botanical identification of the mushroom species consumed remains the only means of unequivocally determining the particular type of intoxication involved, and it is still vitally important to obtain such accurate identification as quickly as possible. Cases involving ingestion of more than one toxic species in which one set of symptoms masks or mimics another set are among many reasons for needing this information. Unfortunately, a number of factors (not discussed here) often make identification of the causative mushroom impossible. In such cases, diagnosis must be based on symptoms alone. In order to rule out other types of food poisoning and

5. Diagnosis of Human Illness:

to conclude that the mushrooms eaten were the cause of the poisoning, it must be established that everyone who ate the suspect mushrooms became ill and that no one who did not eat the mushrooms became ill. Wild mushrooms eaten raw, cooked, or processed should always be regarded as prime suspects. After ruling out other sources of food poisoning and positively implicating mushrooms as the cause of the illness, diagnosis may proceed in two steps. The first step, outlined in Table 1, provides an early indication of the seriousness of the disease and its prognosis.

As described above, the protoplasmic poisons are the most likely to be fatal or to cause irreversible organ damage. In the case of poisoning by the deadly Amanitas, important laboratory indicators of liver (elevated LDH, SGOT, and bilirubin levels) and kidney (elevated uric acid. creatinine, and BUN levels) damage will be present. Unfortunately, in the absence of dietary history, these signs could be mistaken for symptoms of liver or kidney impairment as the result of other causes (e.g., viral hepatitis). It is important that this distinction be made as quickly as possible, because the delayed onset of symptoms will generally mean that the organ has already been damaged. The importance of rapid diagnosis is obvious: victims who are hospitalized and given aggressive support therapy almost immediately after ingestion have a mortality rate of only 10%, whereas those admitted 60 or more hours after ingestion have a 50-90% mortality rate. Table 2 provides more accurate diagnoses and appropriate therapeutic measures. A recent report indicates that amanitins are observable in urine well before the onset of any symptoms, but that laboratory tests for liver dysfunction do not appear until well after the organ has been damaged.

Mushroom poisonings are almost always caused by ingestion of wild mushrooms that have been collected by nonspecialists (although specialists have also been poisoned). Most cases occur when toxic species are confused with edible species, and a useful question to ask of the victims or their mushroom-picking benefactors is the identity of the mushroom they thought they were picking. In the absence of a wellpreserved specimen, the answer to this question could narrow the possible suspects considerably. Intoxication has also occurred when reliance was placed on some folk method of distinguishing poisonous and safe species. Outbreaks have occurred after ingestion of fresh, raw mushrooms, stir-fried mushrooms, home-canned mushrooms. mushrooms cooked in tomato sauce (which rendered the sauce itself toxic, even when no mushrooms were consumed), and mushrooms that were blanched and frozen at home. Cases of poisoning by homecanned and frozen mushrooms are especially insidious because a single outbreak may easily become a multiple outbreak when the preserved toadstools are carried to another location and consumed at another time.

Specific cases of mistaken mushroom identity appears frequently. The Early False Morel *Gyromitra esculenta* is easily confused with the true Morel *Morchella esculenta*, and poisonings have occurred after consumption of fresh or cooked *Gyromitra*. *Gyromitra* poisonings have also occurred after ingestion of commercially available "morels" contaminated with *G. esculenta*. The commercial sources for these fungi (which have not yet been successfully cultivated on a large scale) are field collection of wild morels by semiprofessionals. Cultivated commercial mushrooms of whatever species are almost never

6. Associated Foods:

implicated in poisoning outbreaks unless there are associated problems such as improper canning (which lead to bacterial food poisoning). A short list of the mushrooms responsible for serious poisonings and the edible mushrooms with which they are confused is presented in Table 3. Producers of mild gastroenteritis are too numerous to list here, but include members of many of the most abundant genera, including Agaricus, Boletus, Lactarius, Russula, Tricholoma, Coprinus, Pluteus, and others. The Inky Cap Mushroom (Coprinus atrimentarius) is considered both edible and delicious, and only the unwary who consume alcohol after eating this mushroom need be concerned. Some other members of the genus Coprinus (Shaggy Mane, C. comatus; Glistening Inky Cap, C. micaceus, and others) and some of the larger members of the Lepiota family such as the Parasol Mushroom (Leucocoprinus procera) do not contain coprine and do not cause this effect. The potentially deadly Sorrel Webcap Mushroom (Cortinarius orellanus) is not easily distinguished from nonpoisonous webcaps belonging to the same distinctive genus, and all should be avoided. Most of the psychotropic mushrooms (Inocybe spp., Conocybe spp., Paneolus spp., Pluteus spp.) are in general appearance small, brown, and leathery (the so-called "Little Brown Mushrooms" or LBMs) and relatively unattractive from a culinary standpoint. The Sweat Mushroom (Clitocybe dealbata) and the Smoothcap Mushroom (Psilocybe cubensis) are small, white, and leathery. These small, unattractive mushrooms are distinctive, fairly unappetizing, and not easily confused with the fleshier fungi normally considered edible. Intoxications associated with them are less likely to be accidental, although both C. dealbata and Paneolus foenisicii have been found growing in the same fairy ring area as the edible (and choice) Fairy Ring Mushroom (Marasmius oreades) and the Honey Mushroom (Armillariella mellea), and have been consumed when the picker has not carefully examined every mushroom picked from the ring. Psychotropic mushrooms, which are larger and therefore more easily confused with edible mushrooms, include the Showy Flamecap or Big Laughing Mushroom (Gymnopilus spectabilis), which has been mistaken for Chanterelles (Cantharellus spp.) and for Gymnopilus ventricosus found growing on wood of conifers in western North America. The Fly Agaric (Amanita muscaria) and Panthercap (Amanita pantherina) mushrooms are large, fleshy, and colorful. Yellowish cap colors on some varieties of the Fly Agaric and the Panthercap are similar to the edible Caesar's Mushroom (Amanita caesarea), which is considered a delicacy in Italy. Another edible yellow capped mushroom occasionally confused with yellow A. muscaria and A. pantherina varieties are the Yellow Blusher (Amanita flavorubens). Orange to yellow-orange A. muscaria and A. pantherina may also be confused with the Blusher (Amanita rubescens) and the Honey Mushroom (Armillariella mellea). White to pale forms of A. muscaria may be confused with edible field mushrooms (Agaricus spp.). Young (button stage) specimens of *A. muscaria* have also been confused with puffballs.

7. Relative Frequency of Disease:

Accurate figures on the relative frequency of mushroom poisonings are difficult to obtain. For the 5-year period between 1976 and 1981, 16 outbreaks involving 44 cases were reported to the Centers for Disease Control in Atlanta (Rattanvilay et al. MMWR 31(21): 287-288, 1982). The number of unreported cases is, of course, unknown. Cases are sporadic and large outbreaks are rare. Poisonings tend to be grouped in the spring and fall when most mushroom species are at the height of

their fruiting stage. While the actual incidence appears to be very low, the potential exists for grave problems. Poisonous mushrooms are not limited in distribution as are other poisonous organisms (such as dinoflagellates). Intoxications may occur at any time and place, with dangerous species occurring in habitats ranging from urban lawns to deep woods. As Americans become more adventurous in their mushroom collection and consumption, poisonings are likely to increase.

All humans are susceptible to mushroom toxins. The poisonous species are ubiquitous, and geographical restrictions on types of poisoning that may occur in one location do not exist (except for some of the hallucinogenic LBMs, which occur primarily in the American southwest and southeast). Individual specimens of poisonous mushrooms are also characterized by individual variations in toxin content based on genetics, geographic location, and growing conditions. Intoxications may thus be more or less serious, depending not on the number of mushrooms consumed, but on the dose of toxin delivered. In addition, although most cases of poisoning by higher plants occur in children, toxic mushrooms are consumed most often by adults. Occasional accidental mushroom poisonings of children and pets have been reported, but adults are more likely to actively search for and consume wild mushrooms for culinary purposes. Children are more seriously affected by the normally nonlethal toxins than are adults and are more likely to suffer very serious consequences from ingestion of relatively smaller doses. Adults who consume mushrooms are also more likely to recall what was eaten and when, and are able to describe their symptoms more accurately than are children. Very old, very young, and debilitated persons of both sexes are more likely to become seriously ill from all types of mushroom poisoning, even those types which are generally considered to be mild.

Many idiosyncratic adverse reactions to mushrooms have been reported. Some mushrooms cause certain people to become violently ill, while not affecting others who consumed part of the same mushroom cap. Factors such as age, sex, and general health of the consumer do not seem to be reliable predictors of these reactions, and they have been attributed to allergic or hypersensitivity reactions and to inherited inability of the unfortunate victim to metabolize certain unusual fungal constituents (such as the uncommon sugar, trehalose). These reactions are probably not true poisonings as the general population does not seem to be affected.

The mushroom toxins can with difficulty be recovered from poisonous fungi, cooking water, stomach contents, serum, and urine. Procedures for extraction and quantitation are generally elaborate and time-consuming, and the patient will in most cases have recovered by the time an analysis is made on the basis of toxin chemistry. The exact chemical natures of most of the toxins that produce milder symptoms are unknown. Chromatographic techniques (TLC, GLC, HPLC) exist for the amanitins, orellanine, muscimol/ibotenic acid, psilocybin, muscarine, and the gyromitrins. The amanitins may also be determined by commercially available 3H-RIA kits. The most reliable means of diagnosing a mushroom poisoning remains botanical identification of the fungus that was eaten. An accurate pre-ingestion determination of species will also prevent accidental poisoning in 100% of cases. Accurate post-ingestion analyses for specific toxins when no botanical identification is possible may be essential only in cases of suspected

8. Target Population:

9. Analysis of Foods for Toxins:

poisoning by the deadly *Amanitas*, since prompt and aggressive therapy (including lavage, activated charcoal, and plasmapheresis) can greatly reduce the mortality rate.

Isolated cases of mushroom poisoning have occurred throughout the continental United States. The occurred in Oregon in October,1988, and involved the intoxication of five people who consumed stir-fried Amanita phalloides. The poisonings were severe, and at this writing three of the five people had undergone liver transplants for treatment of amanitin-induced liver failure. Other recent cases have included the July, 1986, poisoning of a family in Philadelphia, by Chlorophyllum molybdites; the September, 1987, intoxication of seven men in Bucks County, PA, by spaghetti sauce which contained Jack O'Lantern mushroom (Omphalotus illudens); and of 14 teenage campers in Maryland by the same species (July, 1987). A report of a North Carolina outbreak of poisoning by False Morel (Gyromitra spp.) appeared in 1986. A 1985 report details a case of Chlorophyllum molybdites that occurred in Arkansas; a fatal poisoning case caused by an amanitin containing Lepiota was described in 1986. In 1981, two Berks County, PA, people were poisoned (one fatally) after ingesting *Amanita* phalloides, while in the same year, seven Laotian refugees living in California were poisoned by Russula spp. In separate 1981 incidents, several people from New York State were poisoned by Omphalotus illudens, Amanita muscaria, Entoloma lividum, and Amanita virosa. An outbreak of gastroenterititis during a banquet for 482 people in Vancouver, British Columbia, was reported by the Vancouver Health Department in June, 1991. Seventy-seven of the guests reported symptoms consisting of early onset nausea (15-30 min), diarrhea (20 min-13 h), vomiting (20-60 min), cramps and bloated feeling. Other symptoms included feeling warm, clamminess, numbness of the tongue and extreme thirst along with two cases of hive-like rash with onset of 3-7 days. Bacteriological tests were negative. This intoxication merits special attention because it involved consumption of species normally considered not only edible but choice. The fungi involved were the morels Morchella esculenta and M. elata (M. angusticeps), which were prepared in a marinade and consumed raw. The symptoms were severe but not life threatening. Scattered reports of intoxications by these species and M. conica have appeared in anecdotal reports for many years.

Numerous other cases exist; however, the cases that appear in the literature tend to be the serious poisonings such as those causing more severe gastrointestinal symptoms, psychotropic reactions, and severe organ damage (deadly *Amanita*). Mild intoxications are probably grossly underreported, because of the lack of severity of symptoms and the unlikeliness of a hospital admission.

For more information on recent outbreaks see the **Morbidity and Mortality Weekly Reports** from CDC.

10. Selected Outbreaks:

Pyrrolizidine Alkaloids

1. Name of Toxin:		n:	Pyrrolizidine Alkaloids Pyrrolizidine Alkaloids Poisoning	
2. Name of Acute Disease:		e Disease:	Pyrrolizidine alkaloid intoxication is caused by consumption of plant material containing these alkaloids. The plants may be consumed as food, for medicinal purposes, or as contaminants of other agricultural crops. Cereal crops and forage crops are sometimes contaminated with pyrrolizidine-producing weeds, and the alkaloids find their way into flour and other foods, including milk from cows feeding on these plants. Many plants from the Boraginaceae, Compositae, and Leguminosae families contain well over 100 hepatotoxic pyrrolizidine alkaloids.	
	3. Normal Course	e of Disease	Most cases of pyrrolizidine alkaloid toxicity result in mod- liver damage. Gastrointestinal symptoms are usually the intoxication, and consist predominantly of abdominal pai and the development of ascites. Death may ensue from more than 2 years after poisoning, but patients may reco- completely if the alkaloid intake is discontinued and the I has not been too severe.	first sign of n with vomiting 2 weeks to over almost
	4. Diagnosis of H	łuman Illness:	Evidence of toxicity may not become apparent until som alkaloid is ingested. The acute illness has been compare Chiari syndrome (thrombosis of hepatic veins, leading to enlargement, portal hypertension, and ascites). Early clir include nausea and acute upper gastric pain, acute abdo distension with prominent dilated veins on the abdomina and biochemical evidence of liver dysfunction. Fever and be present. In some cases the lungs are affected; pulmo and pleural effusions have been observed. Lung damag prominent and has been fatal. Chronic illness from inges amounts of the alkaloids over a long period proceeds thre the liver to cirrhosis, which is indistinguishable from cirrhetiology.	ed to the Budd- b liver nical signs ominal Il wall, fever, d jaundice may onary edema e may be stion of small rough fibrosis of
	5. Associated Fo	oods:	The plants most frequently implicated in pyrrolizidine poi members of the Borginaceae, Compositae, and Legumin Consumption of the alkaloid-containing plants as food, c food, or as medicinals has occurred.	nosae families.
	6. Relative Frequ	uency of Disease:	Reports of acute poisoning in the United States among hardstrively rare. Most result from the use of medicinal prephome remedies. However, intoxications of range animals occur in areas under drought stress, where plants contain are common. Milk from dairy animals can become contain the alkaloids, and alkaloids have been found in the hone bees foraging on toxic plants. Mass human poisonings him other countries when cereal crops used to prepare for contaminated with seeds containing pyrrolizidine alkaloids.	parations as sometimes ining alkaloids iminated with ey collected by have occurred od were d.
	7. Target Popula	ition:	All humans are believed to be susceptible to the hepatot pyrrolizidine alkaloids. Home remedies and consumption in large quantities can be a risk factor and are the most large transfer in the United States.	n of herbal teas

alkaloid poisonings in the United States.

The pyrrolizidine alkaloids can be isolated from the suspect commodity

8. Analysis in Foods:

by any of several standard alkaloid extraction procedures. The toxins are identified by thin layer chromatography. The pyrrolizidine ring is first oxidized to a pyrrole followed by spraying with Ehrlich reagent, which gives a characteristic purple spot. Gas-liquid chromatographic and mass spectral methods also are available for identifying the alkaloids.

There have been relatively few reports of human poisonings in the United States. Worldwide, however, a number of cases have been documented. Most of the intoxications in the USA involved the consumption of herbal preparations either as a tea or as a medicine. The first patient diagnosed in the USA was a female who had used a medicinal tea for 6 months while in Ecuador. She developed typical hepatic veno-occlusive disease, with voluminous ascites, centrilobular congestion of the liver, and increased portal vein pressure. Interestingly, the patient completely recovered within one year after ceasing to consume the tea. Another herbal tea poisoning occurred when Senecio longilobus was mistaken for a harmless plant (called "gordolobo yerba" by Mexican Americans) and used to make herbal cough medicine. Two infants were given this medication for several days. The 2-month-old boy was ill for 2 weeks before being admitted to the hospital and died 6 days later. His condition was first diagnosed as Reve's syndrome, but was changed when jaundice, ascites, and liver necrosis were observed. The second child, a 6-month-old female, had acute hepatocellular disease, ascites, portal hypertension, and a right pleural effusion. The patient improved with treatment; however, after 6 months, a liver biopsy revealed extensive hepatic fibrosis, progressing to cirrhosis over 6 months. Another case of hepatic veno-occlusive disease was described in a 47-year-old nonalcoholic woman who had consumed large quantities of comfrey (Symphytum species) tea and pills for more than one year. Liver damage was still present 20 months after the comfrey consumption ceased.

For more information on recent outbreaks see the **Morbidity and Mortality Weekly Reports** from CDC.

Back to Natural Toxin List

9. Selected Outbreaks:

Phytohaemagglutinin

1. Name of the Toxin:

Phytohaemagglutinin (Kidney Bean Lectin)

- 2. Name of the Acute Disease:
- 3. Nature of the Acute Disease:
- 4. Diagnosis of Human Illness:

5. Foods in Which It Occurs:

6. Frequency of the Disease:

This compound, a <u>lectin</u> or <u>hemagglutinin</u>, has been used by immunologists for years to trigger DNA synthesis in T lymphocytes, and more recently, to activate latent human immunodeficiency virus type 1 (HIV-1, AIDS virus) from human peripheral lymphocytes. Besides inducing mitosis, <u>lectins</u> are known for their ability to agglutinate many mammalian red blood cell types, alter cell membrane transport systems, alter cell permeability to proteins, and generally interfere with cellular metabolism.

Red Kidney Bean (*Phaseolus vulgaris*) Poisoning, Kinkoti Bean Poisoning, and possibly other names.

The onset time from consumption of raw or undercooked kidney beans to symptoms varies from between 1 to 3 hours. Onset is usually marked by extreme nausea, followed by vomiting, which may be very severe. Diarrhea develops somewhat later (from one to a few hours), and some persons report abdominal pain. Some persons have been hospitalized, but recovery is usually rapid (3 - 4 h after onset of symptoms) and spontaneous.

Diagnosis is made on the basis of symptoms, food history, and the exclusion of other rapid onset food poisoning agents (e.g., <u>Bacillus cereus</u>, <u>Staphylococcus aureus</u>, arsenic, mercury, lead, and cyanide).

Phytohaemagglutinin, the presumed toxic agent, is found in many species of beans, but it is in highest concentration in red kidney beans (*Phaseolus vulgaris*). The unit of toxin measure is the hemagglutinating unit (hau). Raw kidney beans contain from 20,000 to 70,000 hau, while fully cooked beans contain from 200 to 400 hau. White kidney beans, another variety of *Phaseolus vulgaris*, contain about one-third the amount of toxin as the red variety; broad beans (*Vicia faba*) contain 5 to 10% the amount that red kidney beans contain.

The syndrome is usually caused by the ingestion of raw, soaked kidney beans, either alone or in salads or casseroles. As few as four or five raw beans can trigger symptoms. Several outbreaks have been associated with "slow cookers" or crock pots, or in casseroles which had not reached a high enough internal temperature to destroy the glycoprotein lectin. It has been shown that heating to 80°C may potentiate the toxicity five-fold, so that these beans are more toxic than if eaten raw. In studies of casseroles cooked in slow cookers, internal temperatures often did not exceed 75°C.

This syndrome has occurred in the United Kingdom with some regularity. Seven outbreaks occurred in the U.K. between 1976 and 1979 and were reviewed (Noah et al. 1980. Br. Med. J. 19 July, 236-7). Two more incidents were reported by Public Health Laboratory Services (PHLS), Colindale, U.K. in the summer of 1988. Reports of this syndrome in the United States are anecdotal and have not been formally published.

The disease course is rapid. All symptoms usually resolve within several hours of onset. Vomiting is usually described as profuse, and the severity of symptoms is directly related to the dose of 7. Usual Course of the Disease and toxin (number of raw beans ingested). Hospitalization has **Some Complications:** occasionally resulted, and intravenous fluids may have to be administered. Although of short duration, the symptoms are extremely debilitating. All persons, regardless of age or gender, appear to be equally susceptible; the severity is related only to the dose ingested. In 8. Target Populations: the seven outbreaks mentioned above, the attack rate was 100%. The difficulty in food analysis is that this syndrome is not well known in the medical community. Other possible causes must be eliminated, such as Bacillus cereus, staphylococcal food 9. Analysis of Food: poisoning, or chemical toxicity. If beans are a component of the suspected meal, analysis is quite simple, and based on hemagglutination of red blood cells (hau). As previously stated, no major outbreaks have occurred in the U.S. Outbreaks in the U.K. are far more common. The syndrome is probably sporadic, affecting small numbers of persons or individuals, and is easily misdiagnosed or never 10. Selected Outbreaks: reported due to the short duration of symptoms. Differences in reporting between the U.S. and U.K. may be attributed to greater use of dried kidney beans in the U.K., or better physician awareness. The U.K. has established a reference laboratory for the quantitation of hemagglutinins from suspected foods. For more information on recent outbreaks see the Morbidity and Mortality Weekly Reports from CDC. 11. Education: NOTE: The following procedure has been recommended by the PHLS to render kidney, and other, beans safe for consumption: Soak in water for at least 5 hours. Pour away the water. Boil briskly in fresh water for at least 10 minutes.

Back to Natural Toxin List

Undercooked beans may be more toxic than raw beans.

Grayanotoxin

Grayanotoxin (formerly known as andromedotoxin, acetylandromedol, 1. Name of Toxin: and rhodotoxin) Honey Intoxication Honey intoxication is caused by the consumption of honey produced from the nectar of rhododendrons. The grayanotoxins cause the intoxication. The specific grayanotoxins vary with the plant species. 2. Name of Acute Disease: These compounds are diterpenes, polyhydroxylated cyclic hydrocarbons that do not contain nitrogen. Other names associated with the disease is rhododendron poisoning, mad honey intoxication or grayanotoxin poisoning. The intoxication is rarely fatal and generally lasts for no more than 24 hours. Generally the disease induces dizziness, weakness, excessive perspiration, nausea, and vomiting shortly after the toxic honey is ingested. Other symptoms that can occur are low blood pressure or shock, bradyarrhythima (slowness of the heart beat associated with an 3. Nature of Disease: irregularity in the heart rhythm), sinus bradycardia (a slow sinus rhythm, with a heart rate less than 60), nodal rhythm (pertaining to a node, particularly the atrioventricular node), Wolff-Parkinson-White syndrome (anomalous atrioventricular excitation) and complete atrioventricular block. The grayanotoxins bind to sodium channels in cell membranes. The binding unit is the group II receptor site, localized on a region of the sodium channel that is involved in the voltage-dependent activation and inactivation. These compounds prevent inactivation; thus, excitable cells (nerve and muscle) are maintained in a state of depolarization, during which entry of calcium into the cells may be facilitated. This action is similar to that exerted by the alkaloids of veratrum and aconite. All of the observed responses of skeletal and heart muscles, nerves,

4. Normal Course of the Disease:

5. Diagnosis of Human Illness:

In humans, symptoms of poisoning occur after a dose-dependent latent period of a few minutes to two or more hours and include salivation, vomiting, and both circumoral (around or near the mouth) and extremity paresthesia (abnormal sensations). Pronounced low blood pressure and sinus bradycardia develop. In severe intoxication, loss of coordination and progressive muscular weakness result. Extrasystoles (a premature contraction of the heart that is independent of the normal rhythm and arises in response to an impulse in some part of the heart other than the sinoatrial node; called also premature beat) and ventricular tachycardia (an abnormally rapid ventricular rhythm with aberrant ventricular excitation, usually in excess of 150 per minute) with

and the central nervous system are related to the membrane effects.

Because the intoxication is rarely fatal and recovery generally occurs within 24 hours, intervention may not be required. Severe low blood pressure usually responds to the administration of fluids and correction of bradycardia; therapy with vasopressors (agents that stimulate contraction of the muscular tissue of the capillaries and arteries) is only rarely required. Sinus bradycardia and conduction defects usually respond to atropine therapy; however, in at least one instance the use

of a temporary pacemaker was required.

both atrioventricular and intraventricular conduction disturbances also may occur. Convulsions are reported occasionally. Grayanotoxin poisoning most commonly results from the ingestion of grayanotoxin-contaminated honey, although it may result from the ingestion of the leaves, flowers, and nectar of rhododendrons. Not all rhododendrons produce grayanotoxins. Rhododendron ponticum grows extensively on the mountains of the eastern Black Sea area of Turkey. This species has been associated with honey poisoning since 401 BC. A number of toxin species are native to the United States. Of particular importance are the western azalea (Rhododendron 6. Associated Foods: occidentale) found from Oregon to southern California, the California rosebay (Rhododendron macrophyllum) found from British Columbia to central California, and Rhododendron albiflorum found from British Columbia to Oregon and in Colorado. In the eastern half of the United States grayanotoxin-contaminated honey may be derived from other members of the botanical family Ericaceae, to which rhododendrons belong. Mountain laurel (Kalmia latifolia) and sheep laurel (Kalmia angustifolia) are probably the most important sources of the toxin. Grayanotoxin poisoning in humans is rare. However, cases of honey intoxication should be anticipated everywhere. Some may be ascribed 7. Relative Frequency of Disease: to a increase consumption of imported honey. Others may result from the ingestion of unprocessed honey with the increased desire of natural foods in the American diet. All people are believed to be susceptible to honey intoxication. The increased desire of the American public for natural (unprocessed) foods, may result in more cases of grayanotoxin poisoning. Individuals 8. Target Population: who obtain honey from farmers who may have only a few hives are at increased risk. The pooling of massive quantities of honey during commercial processing generally dilutes any toxic substance. The grayanotoxins can be isolated from the suspect commodity by 9. Analysis in Foods: typical extraction procedures for naturally occurring terpenes. The toxins are identified by thin layer chromatography.

10. Selected Outbreaks:

Several cases of grayanotoxin poisonings in humans have been documented in the 1980s. These reports come from Turkey and Austria. The Austrian case resulted from the consumption of honey that was brought back from a visit to Turkey. From 1984 to 1986, 16 patients were treated for honey intoxication in Turkey. The symptoms started approximately 1 h after 50 g of honey was consumed. In an average of 24 h, all of the patients recovered. The case in Austria resulted in cardiac arrhythmia, which required a temporal pacemaker to prevent further decrease in heart rate. After a few hours, pacemaker simulation was no longer needed. The Austrian case shows that with increased travel throughout the world, the risk of grayanotoxin poisoning is possible outside the areas of Ericaceae-dominated vegetation, namely, Turkey, Japan, Brazil, United States, Nepal, and British Columbia. In 1983 several British veterinarians reported a incident of grayanotoxin poisoning in goats. One of the four animals died. Post-mortem examination showed grayanotoxin in the rumen contents.

For more information on recent outbreaks see the **Morbidity and Mortality Weekly Reports** from CDC.

Appendices

U.S. Food & Drug Administration Center for Food Safety & Applied Nutrition Foodborne Pathogenic Microorganisms and Natural Toxins Handbook

Infective Dose Information

Most chapters include a statement on infectious dose. These numbers should be viewed with caution for any of the following reasons:

- Often they were extrapolated from epidemiologic investigations.
- They were obtained by human feeding studies on healthy, young adult volunteers.
- They are best estimates based on a limited data base from outbreaks.
- They are worst case estimates.
- Because of the following variables they cannot be directly used to assess risk:

Variables of the Parasite or Microorganism

- Variability of gene expression of multiple pathogenic mechanism(s)
- Potential for damage or stress of the microorganism.
- Interaction of organism with food menstruum and environment
- pH susceptibility of organism
- Immunologic "uniqueness" of the organism
- Interactions with other organisms

Variables of the Host

- Age
- General health
- Pregnancy
- Medications--OTC or prescription
- Metabolic disorders
- Alcoholism, cirrhosis, hemochromatosis
- Malignancy
- Amount of food consumed

- Gastric acidity variation: antacids, natural variation, achlorhydria
- Genetic disturbances
- Nutritional status
- Immune competence
- Surgical history
- Occupation

Because of the complexity of factors involved in making risk decisions, the multidisciplinary Health Hazard Evaluation Board judges each situation on all available facts.

Onset, Duration, and Symptoms of Foodborne Illness

Approximate onset time to symptoms	Predominant symptoms	Associated organism or toxin	
Upper gastrointe	Upper gastrointestinal tract symptoms (nausea, vomiting) occur first or predominate		
Less than 1 h	Nausea, vomiting, unusual taste, burning of mouth.	Metallic salts	
1-2 h	Nausea, vomiting, cyanosis, headache, dizziness, dyspnea, trembling, weakness, loss of consciousness.	Nitrites	
1-6 h mean 2- 4 h	Nausea, vomiting, retching, diarrhea, abdominal pain, prostration.	Staphylococcus aureus and its enterotoxins	
8-16 h (2-4 h emesis possible)	Vomiting, abdominal cramps, diarrhea, nausea.	Bacillus cereus	
6-24 h	Nausea, vomiting, diarrhea, thirst, dilation of pupils, collapse, coma.	Amanita species mushrooms	
Sore throat and r	Sore throat and respiratory symptoms occur		
12-72 h	Sore throat, fever, nausea, vomiting, rhinorrhea, sometimes a rash.	Streptococcus pyogenes	
2-5 days	Inflamed throat and nose, spreading grayish exudate, fever, chills, sore throat, malaise, difficulty in swallowing, edema of cervical lymph node.	Corynebacterium diphtheriae	

Lower gastrointestinal tract symptoms (abdominal cramps, diarrhea) occur first or predominate		
2-36 h, mean 6-12 h	Abdominal cramps, diarrhea, putrefactive diarrhea associated with <i>C. perfringens</i> , sometimes nausea and vomiting.	Clostridium perfringens, Bacillus cereus, Streptococcus faecalis, S. faecium
12-74 h, mean 18-36 h	Abdominal cramps, diarrhea, vomiting, fever, chills, malaise, nausea, headache, possible. Sometimes bloody or mucoid diarrhea, cutaneous lesions associated with V. vulnificus. Yersinia enterocolitica mimics flu and acute appendicitis.	Salmonella species (including S. arizonae), Shigella, enteropathogenic Escherichia coli, other Enterobacteriacae, Vibrio parahaemolyticus, Yersinia enterocolitica, Pseudomonas aeruginosa (?), Aeromonas hydrophila, Plesiomonas shigelloides, Campylobacter jejuni, Vibrio cholerae (O1 and non-O1) V.vulnificus, V. fluvialis
3-5 days	Diarrhea, fever, vomiting abdominal pain, respiratory symptoms.	Enteric viruses
1-6 weeks	Mucoid diarrhea (fatty stools) abdominal pain, weight loss.	Giardia lamblia
1 to several weeks	Abdominal pain, diarrhea, constipation, headache, drowsiness, ulcers, variable often asymptomatic.	Entamoeba histolytica
3-6 months	Nervousness, insomnia, hunger pains, anorexia, weight loss, abdominal pain, sometimes gastroenteritis.	Taenia saginata, T. solium

Neurological symptoms (visual disturbances, vertigo, tingling, paralysis) occur				
	*** <u>SEE GASTROINTESTINAL AND/OR</u> <u>NEUROLOGIC SYMPTOMS</u> (Shellfish Toxins) (this Appendix)	Shellfish toxin		
	Gastroenteritis, nervousness, blurred vision, chest pain, cyanosis, twitching, convulsions.	Organic phosphate		
Less than 1 h	Excessive salivation, perspiration, gastroenteritis, irregular pulse, pupils constricted, asthmatic breathing.	Muscaria-type mushrooms		
	Tingling and numbness, dizziness, pallor, gastro- hemorrhage, and desquamation of skin, fixed eyes, loss of reflexes, twitching, paralysis.	Tetradon (tetrodotoxin) toxins		
1-6 h	Tingling and numbness, gastroenteritis, dizziness, dry mouth, muscular aches, dilated pupils, blurred vision, paralysis.	Ciguatera toxin		
1-011	Nausea, vomiting, tingling, dizziness, weakness, anorexia, weight loss, confusion.	Chlorinated hydrocarbons		
2 h to 6 days, usually 12-36 h	Vertigo, double or blurred vision, loss of reflex to light, difficulty in swallowing. speaking, and breathing, dry mouth, weakness, respiratory paralysis.	Clostridium botulinum and its neurotoxins		
More than 72 h	Numbness, weakness of legs, spastic paralysis, impairment of vision, blindness, coma.	Organic mercury		
14.010 (1011 / 2 11	Gastroenteritis, leg pain, ungainly high- stepping gait, foot and wrist drop.	Triorthocresyl phosphate		
Allergic symptom	rgic symptoms (facial flushing, itching) occur			
	Headache, dizziness, nausea, vomiting, peppery taste, burning of throat, facial swelling and flushing, stomach pain, itching of skin.	Histamine (scombroid)		
Less than 1 h	Numbness around mouth, tingling sensation, flushing, dizziness, headache, nausea.	Monosodium glutamate		
	Flushing, sensation of warmth, itching, abdominal pain, puffing of face and knees.	Nicotinic acid		

Generalized infection symptoms (fever, chills, malaise, prostration, aches, swollen lymph nodes) occur				
4-28 days, mean 9 days	Gastroenteritis, fever, edema about eyes, perspiration, muscular pain, chills, prostration, labored breathing.	Trichinella spiralis		
7-28 days, mean 14 days	Malaise, headache, fever, cough, nausea, vomiting, constipation, abdominal pain, chills, rose spots, bloody stools.	Salmonella typhi		
10-13 days	Fever, headache, myalgia, rash.	Toxoplasma gondii		
10-50 days, mean 25- 30 days	Fever, malaise, lassitude, anorexia, nausea, abdominal pain, jaundice.	Etiological agent not yet isolated probably viral		
Varying periods (depends on specific illness)	Fever, chills, head- or joint ache, prostration, malaise, swollen lymph nodes, and other specific symptoms of disease in question.	Bacillus anthracis, Brucella melitensis, B. abortus, B. suis, Coxiella burnetii, Francisella tularensis, <u>Listeria monocytogenes</u> , Mycobacterium tuberculosis, Mycobacterium species, Pasteurella multocida, Streptobacillus moniliformis, <u>Campylobacter jejuni</u> , Leptospira species.		
Gastrointestin	Gastrointestinal and/or Neurologic Symptoms - (Shellfish Toxins)			
0.5 to 2 h	Tingling, burning, numbness, drowsiness, incoherent speech, respiratory paralysis	Paralytic Shellfish Poisoning (PSP) (saxitoxins)		
2-5 min to 3- 4 h	Reversal of hot and cold sensation, tingling; numbness of lips, tongue & throat; muscle aches, dizziness, diarrhea, vomiting	Neurotoxic Shellfish Poisoning (NSP) (brevetoxins)		
30 min to 2- 3 h	Nausea, vomiting, diarrhea, abdominal pain, chills, fever	Diarrheic Shellfish Poisoning (DSP) (dinophysis toxin, okadaic acid, pectenotoxin, yessotoxin)		
24 h (gastrointesti nal) to 48 h (neurologic)	Vomiting, diarrhea, abdominal pain, confusion, memory loss, disorientation, seizure, coma	Amnesic Shellfish Poisoning (ASP) (domoic acid)		

January 1992

Factors Affecting the Growth of Microorganisms in Foods

Food is a chemically complex matrix, and predicting whether, or how fast, microorganisms will grow in any given food is difficult. Most foods contain sufficient nutrients to support microbial growth. Several factors encourage, prevent, or limit the growth of microorganisms in foods, the most important are a_w, pH, and temperature.

<u>a_w</u>: (Water Activity or Water Availability). Water molecules are loosely oriented in pure liquid water and can easily rearrange. When other substances (solutes) are added to water, water molecules orient themselves on the surface of the solute and the properties of the solution change dramatically. The microbial cell must compete with solute molecules for free water molecules. Except for *Staphylococcus aureus*, bacteria are rather poor competitors, whereas molds are excellent competitors. a_w varies very little with temperature over the range of temperatures that support microbial growth. A solution of pure water has an a_w of 1.00. The addition of solute decreases the a_w to less than 1.00.

Water Activity of Various NaCl Solutions

Percent NaCl (w/v)	Molal	Water Activity (a _w)
0.9	0.15	0.995
1.7	0.30	0.99
3.5	0.61	0.98
7.0	1.20	0.96
10.0	1.77	0.94
13.0	2.31	0.92
16.0	2.83	0.90
22.0	3.81	0.86

The a_w of a solution may dramatically affect the ability of heat to kill a bacterium at a given temperature. For example, a population of *Salmonella typhimurium* is reduced tenfold in 0.18 minutes at 60°C if the a_w of the suspending medium is 0.995. If the a_w is lowered to 0.94, 4.3 min are required at 60°C to cause the same tenfold reduction.

An a_w value stated for a bacterium is generally the minimum a_w which supports growth. At the minimum aw, growth is usually minimal, increasing as the a_w increases. At a_w values below the minimum for growth, bacteria do not necessarily die, although some proportion of the population does die. The bacteria may remain dormant, but infectious. Most importantly, a_w is only one factor, and the other factors (e.g., pH, temperature) of the food must be considered. It is the interplay between factors that ultimately

determines if a bacterium will grow or not. The a_w of a food may not be a fixed value; it may change over time, or may vary considerably between similar foods from different sources.

<u>pH</u>: (hydrogen ion concentration, relative acidity or alkalinity). The pH range of a microorganism is defined by a minimum value (at the acidic end of the scale) and a maximum value (at the basic end of the scale). There is a pH optimum for each microorganism at which growth is maximal. Moving away from the pH optimum in either direction slows microbial growth.

A range of pH values is presented here, as the pH of foods, even those of a similar type, varies considerably. Shifts in pH of a food with time may reflect microbial activity, and foods that are poorly buffered (i.e., do not resist changes in pH), such as vegetables, may shift pH values considerably. For meats, the pH of muscle from a rested animal may differ from that of a fatigued animal.

A food may start with a pH that precludes bacterial growth, but as a result of the metabolism of other microbes (yeasts or molds), pH shifts may occur and permit bacterial growth.

<u>Temperature</u>. Temperature values for microbial growth, like pH values, have a minimum and maximum range with an optimum temperature for maximal growth. The rate of growth at extremes of temperature determines the classification of an organism (e.g., psychrotroph, thermotroph). The optimum growth temperature determines its classification as a thermophile, mesophile, or psychrophile.

INTERPLAY OF FACTORS AFFECTING MICROBIAL GROWTH IN FOODS: Although each of the major factors listed above plays an important role, the interplay between the factors ultimately determines whether a microorganism will grow in a given food. Often, the results of such interplay are unpredictable, as poorly understood synergism or antagonism may occur. Advantage is taken of this interplay with regard to preventing the outgrowth of *C. botulinum*. Food with a pH of 5.0 (within the range for *C. botulinum*) and an a_w of 0.935 (above the minimum for *C. botulinum*) may not support the growth of this bacterium. Certain processed cheese spreads take advantage of this fact and are therefore shelf stable at room temperature even though each individual factor would permit the outgrowth of *C. botulinum*.

Therefore, predictions about whether or not a particular microorganism will grow in a food can, in general, only be made through experimentation. Also, many microorganisms do not need to multiply in food to cause disease.

<u>Factors</u> affecting growth of pathogens in foods.
